### Abstract

A family of integer programs is considered whose right-hand-sides lie on a given line segment L. This family is called a parametric integer program(PIP). Solving a (PIP) means finding an optimal solution for every program in the family. It is shown how a simple generalization of the conventional branch-and-bound approach to integer programming makes it possible to solve such a (PIP). The usual bounding test is extended from a comparison of two point values to a comparison of two functions defined on the line segment L. The method is illustrated on a small example and computational results for some larger problems are reported.

#### Introduction

The purpose of this paper is to show how a simple generalization of the conventional branch-and-bound approach to integer programming makes it possible to solve a parametric integer program. Following Nauss [6] we shall call the family of programs

$$(P_{\theta})$$
 max  $\sum_{j=1}^{n} r_{j} x_{j}$ 

subject to

$$\sum_{j=1}^{n} a_{ij} x_{j} \leq b_{i} + \theta d_{i}$$

$$1 \leq i \leq m$$

$$x_j \in \{0,1\}$$
  $1 \le j \le n$ 

for  $0 \le \theta \le 1$  a single parametric integer program (PIP). By "solving" (PIP) we shall mean obtaining an optimal solution of  $(P_{\theta})$  for every  $0 \le \theta \le 1$  for which  $(P_{\theta})$  is feasible. We assume that  $(P_{\theta})$  is feasible for at least one value of  $\theta$ .

Parametric integer programming has only recently emerged as a topic of research. The pioneering papers include Noltemeier [7], Roodman [9,10], Piper and Zoltners [8], and Bowman [1]. Nauss [6] has reviewed this earlier work and contributed many new results for parameterizations of the objective function. The present paper, which has grown out of the authors' work on synthesizing dynamic programming with branch-and-bound [3,4,5], is devoted to the right-hand-side case.

In parametric <u>linear</u> programming, the first step is to solve  $(P_0)$ , i.e.  $(P_\theta)$  for  $\theta$ =0. Then the direction vector d= $(d_1, \ldots, d_m)$  is specified and the analysis is performed by driving  $\theta$  from 0 to 1. Critical values of  $\theta$  and new optimal solutions are identified one at a time as  $\theta$  increases. In the procedure for parametric <u>integer</u> programming to be presented here, the direction d must be specified in advance. The (PIP) is solved in one branch-and-bound search. The usual bounding test is modified so that a partial solution is eliminated only if none of its descendants is optimal for any  $(P_\theta)$ ,  $0 \le \theta \le 1$ . This means that some partial solutions must be retained that could otherwise be eliminated if only  $(P_0)$  were of interest. The severity of the resulting computational burden depends on the magnitude of d.

The organization of the paper is as follows. A prototype branch- and-bound algorithm for  $(P_0)$  is presented in Section 2. The lower bound and upper bound functions are developed in Sections 3 and 4, respectively. The modified branch-and-bound algorithm for (PIP) is given in Section 5 and applied to a sample problem in Section 6. Computational experience with the algorithm is reported in Section 7.

### A prototype branch-and-bound algorithm

We shall draw upon the framework and terminology of Geoffrion and Marsten [2] to describe a simple linear programming based branch-and-bound algorithm for  $(P_0)$ . Problem  $(P_0)$  is separated, by fixing variables at zero

and one, into smaller candidate problems (CP $^q$ ). Each candidate problem has an associated set of fixed variables  $\mathbf{F}^q \subseteq \mathbf{J} = \{1, \ldots, n\}$  and partial solution  $\mathbf{x}^q$ . That is, (CP $^q$ ) is defined by the conditions  $\mathbf{x}_j = \mathbf{x}_j^q$  for  $j \in \mathbf{F}^q$ . The current set of candidate problems is called the candidate list. If any feasible solutions of (P $_0$ ) are known, the best of these is called the incumbent and its value denoted by LB. If we let  $\mathbf{J}^q = \mathbf{J} - \mathbf{F}^q$  be the set of "free" variables and

$$\beta^{\mathbf{q}} = \sum_{\mathbf{j} \in \mathbf{F}^{\mathbf{q}}} A_{\mathbf{j}} \mathbf{x}_{\mathbf{j}}^{\mathbf{q}}$$

where  $\mathbf{A}_{\mathbf{j}}$  is the jth column of  $\mathbf{A}_{\mathbf{j}}$  then a typical candidate problem may be written as

An upper bound on the value of  $(CP^q)$  is obtained by solving its LP relaxation  $(CP_R^q)$ . It is also helpful to compute a lower bound on the value of  $(CP^q)$ . This can be done by using a heuristic to find a feasible solution of  $(CP^q)$ . This feasible solution, if it is better than the incumbent, becomes the new incumbent. A prototype branch-and-bound algorithm may now be described as follows.

- Step 1. Place  $(P_0)$  in the candidate list and set LB =  $\infty$  .
- Step 2. If the candidate list is empty, stop. If there is an incumbent, it is optimal for  $(P_0)$ . Otherwise  $(P_0)$  is infeasible.
- Step 3. Select a candidate problem and remove it from the candidate list. Call it  $(\mathbb{CP}^q)$ .
- Step 4. Solve the linear program ( $\mathbb{CP}^q_R$ ). Let  $\mathbb{UB}^q$  denote its optimal value.
- Step 5. If  $UB^q \leq LB$ , go to Step 2.
- Step 6. If the optimal solution of  $(CP_R^q)$  is all integer, make this solution the new incumbent, set LB = UB $^q$ , and go to Step 2.
- Step 7. Use a heuristic to find a feasible solution of  $(\mathbb{CP}^q)$ . Let  $\mathbb{H}^q$  denote its value. If  $\mathbb{H}^q > \mathbb{LB}$ , then make this solution the new incumbent and set  $\mathbb{LB} = \mathbb{H}^q$ .
- Step 8. Separate (CP<sup>q</sup>) into two new candidate problems (CP<sup>q</sup>) and (CP<sup>q</sup>) by choosing  $p \in J^q$  and setting  $F^q = F^q = F^q \cup \{p\}$ ,  $x_p^q = 0$ ,  $x_p^q = 1$ .

  Place (CP<sup>q</sup>) and (CP<sup>q</sup>) in the candidate list and return to Step 2.

A great many variations on this pattern are described in [2], but this prototype will suffice for our purposes. Step 5 is the bounding test. If this test is satisfied, then no descendant of  $\mathbf{x}^q$  is better than the incumbent. Notice that the bounding test includes the case where  $(\mathbf{CP}^q)$ , and hence  $(\mathbf{CP}^q)$ , is infeasible since then  $\mathbf{UB}^q = -\infty$ . If  $(\mathbf{CP}^q)$  does not have to be separated at Step 8, then we say that it has been fathomed. This occurs if  $(\mathbf{CP}^q)$  passes the bounding test or if  $(\mathbf{CP}^q)$  has an all integer solution. Step 7, the heuristic, is optional. Its purpose is to strengthen the bounding test by improving the incumbent and increasing LB.

The modifications that must be made to this prototype algorithm to solve (PIP) are confined to Steps 5, 6, and 7. The notion of the incumbent must be generalized from a single value LB to a function LB( $\theta$ ) defined on  $0 \le \theta \le 1$ . The upper bound must also be expressed as a function of  $\theta$ : UB<sup>q</sup>( $\theta$ ). The bounding test then becomes a comparison of two functions on the interval  $0 \le \theta \le 1$  rather than just a point comparison for  $\theta = 0$ .

# The optimal return and lower bound functions.

In this section we shall investigate the behavior of the optimal value of an integer program as a function of its right-hand-side. Let the optimal return function

$$f(b') = \max rx$$
 subject to  $Ax \le b'$   
 $x \in \{0,1\}$ 

be defined for b'  $\in$  R<sup>m</sup>. It is apparent that f(b') is nondecreasing in each component of b'. Let  $\{x^k \mid k \in K\}$  be the set of all feasible solutions of (PIP), i.e. of all  $(P_\theta)$  for  $0 \le \theta \le 1$ . For each  $k \in K$ , define the step function

$$f^{k}(b') = \begin{cases} \sum_{j=1}^{n} r_{j}x_{j}^{k} & \text{if } b' \ge \sum_{j=1}^{n} A_{j}x_{j}^{k} \\ -\infty & \text{otherwise} \end{cases}$$

for all b'  $\in R^m$ .

The optimal return function f(b') is the pointwise maximum of this finite collection of nondecreasing step functions

$$f(b') = \max \{f^k(b') \mid k \in K\}$$

and is therefore itself a nondecreasing step function.

Now suppose that the solutions  $\{x \mid k \in \overline{K}\}$  are known, where  $\overline{K} \subseteq K$ . A lower approximation of f(b') may be constructed from these known solutions, namely

$$\bar{f}(b') = \max \{f^k(b') \mid k \in \bar{K}\}.$$

Clearly  $\overline{f}(b')$  is also a nondecreasing step function and is a lower bound function for f(b'), i.e.  $\overline{f}(b') \leq f(b')$  for all  $b' \in \mathbb{R}^m$ . The approximation can be improved as new feasible solutions are discovered.

We are interested in a particular "slice" of f(b') and  $\overline{f}(b')$ : the line segment  $\{b+\theta d \mid 0 \le \theta \le 1\}$  where b is the right-hand-side of  $(P_0)$  and d is the given direction vector. Define  $g(\theta)=f(b+\theta d)$  and  $LB(\theta)=\overline{f}(b+\theta d)$  for  $0 \le \theta \le 1$ . Then  $g(\theta)$  and  $LB(\theta)$  are both step functions and  $LB(\theta) \le g(\theta)$  for all  $0 \le \theta \le 1$ . If  $d \ge 0$ , then  $g(\theta)$  and  $LB(\theta)$  are both nondecreasing. (See Figure 1). There is at least one optimal solution of (PIP) associated with each step of  $g(\theta)$ . Solving (PIP) is equivalent to constructing  $g(\theta)$  by finding at least one x solution for each of its steps.

The procedure for constructing LB( $\theta$ ) from the known feasible solutions is as follows. For each k  $\in$   $\overline{K}$  define

$$\theta_1^k = \min \left\{ \theta \mid \sum_{j=1}^n A_j x_j^k \le b + \theta d \right\}$$
 (3.1)

$$\theta_2^k = \max \left\{ \theta \mid \sum_{j=1}^n A_j x_j^k \le b + \theta d \right\}$$
 (3.2)

where  $\theta_1^k = \theta_2^k = +\infty$  if the indicated set is empty. Then

$$LB^{k}(\theta) = \begin{cases} \sum_{j=1}^{n} r_{j}x_{j}^{k} & \text{if } \theta_{1}^{k} \leq \theta \leq \theta_{2}^{k} \\ -\infty & \text{otherwise} \end{cases}$$
(3.3)

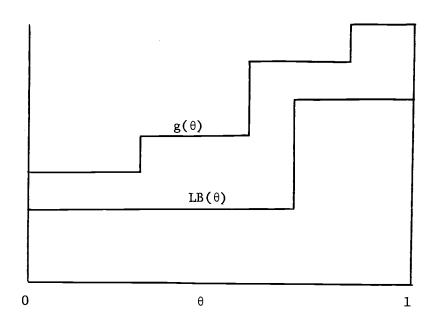

Figure 1. Typical  $g(\theta)$  and  $LB(\theta)$  functions.

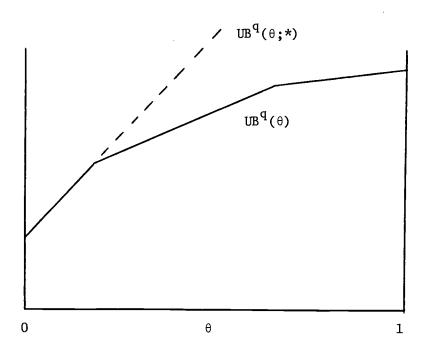

Figure 2. Typical  ${\tt UB}^q(\theta)$  and  ${\tt UB}^q(\theta;*)$  functions.

and

$$LB(\theta) = \max\{LB^{k}(\theta) \mid k \in \overline{K}\}. \tag{3.4}$$

The solutions which determine LB( $\theta$ ) will be called the incumbents. Each one is incumbent for a particular interval of  $\theta$ .

# 4. The upper bound functions.

Consider a given partial solution  $x^q$ . In order to demonstrate that no descendant of  $x^q$  could be optimal for any  $(P_\theta)$ , we need an upper bound on the return achieved by any descendant and this upper bound must depend on  $\theta$ . Such an upper bound can be obtained by introducing  $(\theta d)$  into the relaxed candidate problem  $(CP_R^q)$ . Define

$$UB^{q}(\theta) = \sum_{j \in F^{q}} r_{j}x_{j}^{q} + \max \sum_{j \in J^{q}} r_{j}x_{j}$$

subject to

$$\sum_{\mathbf{j} \in J^{\mathbf{q}}} \mathbf{a}_{\mathbf{i}\mathbf{j}} \mathbf{x}_{\mathbf{j}} \leq \mathbf{b}_{\mathbf{i}} + \theta \mathbf{d}_{\mathbf{i}} - \beta_{\mathbf{i}}^{\mathbf{q}}$$
 
$$1 \leq \mathbf{i} \leq \mathbf{m}$$
 
$$\mathbf{j} \in J^{\mathbf{q}}$$
 
$$0 \leq \mathbf{x}_{\mathbf{j}} \leq 1$$

so that  ${\tt UB}^q(0) = {\tt UB}^q$ . It is well known that  ${\tt UB}^q(\theta)$  is concave and piecewise linear on  $0 \le \theta \le 1$ . The function  ${\tt UB}^q(\theta)$  could be obtained explicitly by ordinary parametric linear programming. The computational burden involved in doing this for every candidate problem could be quite substantial, however. Fortunately any dual feasible solution of  $({\tt CP}^q_R)$  can be used to construct a linear upper bound function for  ${\tt UB}^q(\theta)$ . An optimal dual solution of  $({\tt CP}^q_R)$ , barring degeneracy, yields the first linear segment of  ${\tt UB}^q(\theta)$ .

By linear programming duality we know that;

$$UB^{q}(\theta) = \sum_{j \in F^{q}} r_{j}x_{j}^{q} + \min \sum_{i=1}^{m} u_{i}(b_{i} + \theta d_{i} - \beta_{i}^{q}) + \sum_{j=1}^{n} v_{j}$$

subject to 
$$\sum_{i=1}^m u_i a_{ij} + v_j \ge r_j \qquad \qquad j \in J^c$$
 
$$u_i \ge 0 \qquad \qquad 1 \le i \le m$$
 
$$v_i \ge 0 \qquad \qquad 1 \le j \le n$$

For notational convenience we have included all of the  $v_j$  variables, even though  $v_j = 0$  for  $j \in F^q$  in any optimal solution. Let  $\textbf{D}^q$  denote the dual feasible region

$$D^{q} = \{(u,v) \ge 0 \mid \sum_{i=1}^{m} u_{i}a_{ij} + v_{j} \ge r_{j} \text{ for } j \in J^{q}\}.$$

Since the primal variables are all bounded and at least one  $(P_{\theta})$  is feasible, we may conclude that  $D^q$  is non-empty. Let  $\{(u^t, v^t) | t \in T^q\}$  and  $\{(y^s, z^s) | s \in S^q\}$  denote the sets of extreme points and extreme rays, respectively, of  $D^q$ . Taking  $e=(1, \ldots, 1)$  we have

$$UB^{q}(\theta) \leq \sum_{j \in F^{q}} r_{j} x_{j}^{q} + u^{t}(b + \theta d - \beta^{q}) + v^{t}e$$

for all  $t \in T^q$ , with equality if  $(u^t, v^t)$  is optimal for the objective function  $u(b+\theta d-\beta^q)$  + ve. As a function of  $\theta$  then, the return achieved by any descendant of  $x^q$  is bounded above by:

$$UB^{q}(\theta;t) = (u^{t}d)\theta + \left[\sum_{j \in F^{q}} r_{j}x_{j}^{q} + u^{t}(b-\beta^{q}) + v^{t}e\right]$$

for any  $t \in T^q$ . This is a linear function of  $\theta$  and, since  $u^t \ge 0$ , it is nondecreasing if  $d \ge 0$ .

In the modified branch-and-bound algorithm for (PIP), linear programming is applied to  $(CP_R^q)$  as usual. The functions  $UB^q(\theta;t)$  are obtained at no extra cost. The function obtained from an optimal dual solution will be denoted  $UB^q(\theta;*)$ . Barring degeneracy,  $UB^q(\theta;*)$  coincides with the first linear segment of  $UB^q(\theta)$ . (See Figure 2). As in conventional branch-and-bound, if the dual simplex method is used, then suboptimal dual solutions can be used to perform additional weaker tests.

If (CP\_R^q) is infeasible, then the simplex method will terminate with an extreme point (u^t, v^t)  $\geq$  0 and an extreme ray (y^S, z^S)  $\geq$  0, such that

$$y^{s}(b-\beta^{q}) + z^{s}e < 0.$$

If  $y^s d \le 0$ , then we may conclude that  $UB^q(\theta) = -\infty$  for all  $0 \le \theta \le 1$ . If  $y^s d > 0$ , then  $UB^q(\theta) = -\infty$  for  $0 \le \theta \le \theta *$  and  $UB^q(\theta) \le UB^q(\theta;t)$  for  $\theta * \le \theta \le 1$ , where

$$\theta * = \frac{-y^{s}(b-\beta^{q}) - z^{s}e}{v^{s}d}$$

### 5. A branch-and-bound algorithm for (PIP).

Now that the upper and lower bound functions have been derived, the generalized bounding test may be stated. The partial solution  $\mathbf{x}^q$  does not have a descendant that is better than an incumbent if

$$UB^{q}(\theta) \leq LB(\theta)$$

for all  $0 \le \theta \le 1$ 

or if

$$UB^{q}(\theta;t) \leq LB(\theta)$$

for all  $0 \le \theta \le 1$ 

for some  $t \in T^q$ . This test is the basis for a modified branch-and-bound algorithm that can solve (PIP).

- Step 1. Place  $(P_0)$  in the candidate list and set  $LB(\theta) = -\infty$  for  $0 \le \theta \le 1$ .
- Step 2. If the candidate list is empty, stop. LB( $\theta$ ) = g( $\theta$ ) for  $0 \le \theta \le 1$ .
- Step 3. Select a candidate problem and remove it from the candidate list. Call it  $(\mathbb{CP}^q)$ .
- Step 4. Solve  $(CP_R^q)$ . If it is infeasible, obtain the appropriate dual extreme point (u\*, v\*) and extreme ray (y\*, z\*). Otherwise obtain an optimal dual solution (u\*, v\*).
- Step 5. I.  $(CP_R^q)$  infeasible.
  - (a)  $y*d \le 0$ . Go to Step 2.
  - (b) y\*d > 0. Set  $\theta* = [-y*(b-\beta^q)-z*e] / y*d$ . If  $UB^q(\theta;*) \le LB(\theta)$  for all  $\theta*\le \theta \le 1$ , go to Step 2.
  - II. ( $\operatorname{CP}^q_R$ ) feasible.

If  $UB^q(\theta;*) \le LB(\theta)$  for all  $0 \le \theta \le 1$ , go to Step 2.

- Step 6. If the optimal primal solution of  $(CP_R^q)$  is all integer, use it to update  $LB(\theta)$ .
- Step 7. Use a heuristic to find feasible solutions of (CP  $^q$ ) with right-hand-side (b+ $\theta$ d) for several values of  $\theta$ . Use these feasible solutions to update LB( $\theta$ ).
- Step 8. Separate (CP<sup>q</sup>) into two new candidate problems (CP<sup>q</sup>) and (CP<sup>q</sup>) by choosing  $p \in J^q$  and setting  $F^q = F^q = F^q \cup \{p\}$   $x_p^q = 0$ ,  $x_p^q = 1$ . Place (CP<sup>q</sup>) and (CP<sup>q</sup>) in the candidate list and return to Step 2.

The validity of the generalized bounding test insures that an optimal solution for every  $(P_{\theta})$ ,  $0 \le \theta \le 1$ , will be found by the search. At worst, an optimal solution may not be discovered until the bottom of the branch-and-bound tree is reached  $(F^q=J)$ . This guarantees that  $LB(\theta)$  will coincide with  $g(\theta)$  by the time the algorithm is finished. It remains only to show how the optimal solutions are identified.

Let  $\{\mathbf{x}^k | \mathbf{k} \in \overline{K}\}$  be the set of incumbents when the algorithm terminates. Let  $\theta \in [0,1]$  and suppose that  $(P_\theta)$  is feasible,  $g(\theta) > -\infty$ . From the construction of  $LB(\theta)$ , (3.1) - (3.4), we know that there is some  $\mathbf{k} \in \overline{K}$  such that

$$g(\theta) = LB(\theta)$$

$$= LB^{k}(\theta)$$

$$= \sum_{j=1}^{n} r_{j}x_{j}^{k} > -\infty.$$

Furthermore,  $LB^k(\theta) > -\infty$  means that  $\theta_1^k \leq \theta \leq \theta_2^k$  , or equivalently that

$$\sum_{j=1}^{n} A_{j} x_{j}^{k} \leq b + \theta d.$$

Since  $x^k$  is feasible for  $(P_\theta)$  and its return is equal to  $g(\theta)$ , it follows that  $x^k$  is optimal for  $(P_\theta)$ . To summarize, if  $k \in \overline{K}$  and  $\theta \in [0,1]$ , then  $x^k$  is optimal for  $(P_\theta)$  if and only if

i) 
$$\sum_{j=1}^{n} A_{j} x_{j}^{k} \leq b + \theta d$$

and ii) 
$$\sum_{j=1}^{n} r_{j} x_{j}^{k} = g(\theta) .$$

At Step 6, in contrast to the prototype algorithm,  $\mathbf{x}^q$  is not fathomed when the optimal primal solution of  $(\mathbf{CP}^q_R)$  is all integer. This is because  $\mathbf{x}^q$  may have other descendants which are optimal for  $\theta > 0$ . The use of heuristics at Step 7, while in principle optional, is an important part of the algorithm since integer solutions of  $(\mathbf{CP}^q_R)$  can only yield  $\mathtt{LB}(\theta) = \mathtt{LB}(0)$  for  $\mathbf{0} \le \theta \le 1$ . The heuristics are needed to produce stronger values of  $\mathtt{LB}(\theta)$  for  $\theta > 0$ .

As with the prototype algorithm, the above procedure will admit considerable variation and refinement. If the dual simplex method is used, then suboptimal dual solutions can be used to perform additional bounding tests. Cutting planes can be generated for any candidate problem to give stronger upper bound functions. Parametric linear programming can be used to generate more than the first segment of  $UB^q(\theta)$ . If a candidate problem with an all-integer LP solution has to be separated at Step 8, then the same LP solution is optimal for one of the two new candidates and does not have to be recomputed. Extensive experimentation will be required to determine the most effective computational tactics.

#### 6. Example

In this section the algorithm will be applied to a simple example. In order to illustrate all of the different cases that can arise, the parameterization will be done over a relatively large interval. The test problem is

$$\max \ 10x_1 + 15x_2 + 10x_3 + 5x_4$$

subject to

$$2x_1 + 3x_2 + 5x_3 + 1x_4 \le 4 + 04$$

$$4x_1 + 2x_2 + 1x_3 + 1x_4 \le 4 + 04$$

$$x_j \in \{0,1\} \qquad 1 \le j \le 4$$

Thus b=(4,4), d=(4,4) and increasing  $\theta$  from zero to one amounts to doubling the right-hand-side. A picture of the optimal return function f(b') is given in Figure 3. The dashed line indicates the line segment of interest:  $\{b+\theta d \mid 0 \le \theta \le 1\}$ . It is clear from this picture that three optimal solutions must be found, with values of 20, 25, and 30. These solutions are (0,1,0,1), (1,1,0,0), and (1,1,0,1) respectively. The  $g(\theta)$  function, shown in Figure 4, is

$$g(\theta) = \begin{cases} 20 \text{ for } 0 \le \theta < 1/2 \\ 25 \text{ for } 1/2 \le \theta < 3/4 \\ 30 \text{ for } 3/4 \le \theta \le 1. \end{cases}$$

The optimal LP solution of  $(P_0)$  is x=(1/2,1,0,0), u=(5,0), v=(0) with value UB<sup>0</sup>=20. The rounded down solution has value 15 and is feasible for  $\theta \ge 0$ ; the rounded up solution has value 25 and is feasible for  $\theta \ge 1/2$ .

This provides an initial lower bound function:

LB(
$$\theta$$
) =  $\begin{cases} 15 \text{ for } 0 \le \theta < 1/2 \\ 25 \text{ for } 1/2 \le \theta \le 1. \end{cases}$ 

The complete branch-and-bound tree is displayed in Figure 5. The nodes will be discussed in the order in which they were created.

Node 1. LP solution: x=(0,1,0,1), u=(5,0), v=(0),  $UB^1=20$ .  $UB^1(\theta;*)=20\theta+20$ . The LP solution is all integer and is feasible for  $\theta \ge 0$ . Therefore the lower bound function may be improved:

LB(
$$\theta$$
) = 
$$\begin{cases} 20 & \text{for } 0 \le \theta < 1/2 \\ 25 & \text{for } 1/2 \le \theta \le 1. \end{cases}$$

The bounding test for node 1 is shown in Figure 6. Node 1 is not fathomed.

Node 2. LP solution: x=(1,0,0,0), u=(0,10), v=(0),  $UB^2=10$ .  $UB^2(\theta;*)=40\theta+10$ . The bounding test, shown in Figure 7, is not successful. Notice that if we were only interested in solving  $(P_0)$  we would be finished. Node 1 has an all integer solution with value 20 and node 2 has upper bound  $UB^2=10<20=LB(0)$ .

Node 3. LP solution: x=(0,0,3/5,1), u=(2,0), v=(0,0,0,3),  $UB^3=11$ .  $UB^3(\theta;*)=8\theta+11$ . The bounding test, shown in Figure 8, is successful and node 3 is fathomed.

Node 4. Same as node 1, since optimal LP solution at node 1 has  $x_2 = 1$ .

Node 5. Same as node 2, since optimal LP solution at node 2 has  $x_2 = 0$ .

Node 6. LP is infeasible. The dual extreme point is u=(0,10), v=(0) and the extreme ray is y=(0,1), z=(0). The critical value of  $\theta$  is  $(-y(b-\beta^6)-ze)/yd=1/2$ . Thus  $UB^6(\theta)=-\infty$  for  $0\leq\theta<1/2$  and  $UB^6(\theta;*)=40\theta+5$  for  $1/2\leq\theta\leq1$ . The bounding test is shown in Figure 9.

Node 7. Same as nodes 1 and 4, since optimal LP solution for node 4 has  $x_3=0$ .

Node 8. LP is infeasible. The dual extreme point is u=(5,0), v=(0) and the extreme ray is y=(1,0), z=(0). The critical value of  $\theta$  is  $(-y(b-\beta^8)-ze)/yd=1$ , so  $UB^8(\theta) = -\infty$  on  $0 \le \theta \le 1$  and node 8 is fathomed.

Node 9. Same as nodes 2 and 5, since optimal LP solution for node 5 has  $x_3=0$ .

Node 10. LP is infeasible. The dual extreme point is u=(5,0), v=(0) and the extreme ray is y=(1,0), z=(0). The critical value of  $\theta$  is  $(-y(b-\beta^{10})-ze)/yd=3/4$ . Thus  $UB^{10}(\theta)=-\infty$  for  $0\le\theta<3/4$  and  $UB^{10}(\theta;*)=20\theta+5$  for  $3/4\le\theta\le1$ . Node 10 is therefore fathomed. See Figure 10.

Node 11. LP is infeasible. The dual extreme point is u=(0,5), v=(0) and the extreme ray is y=(0,1), z=(0). The critical value of  $\theta$  is  $(-y(b-\beta^{11})-ze)/yd=1/2$ . Thus UB<sup>11</sup>( $\theta$ ) = -  $\infty$  for  $0 \le \theta < 1/2$  and UB<sup>11</sup>( $\theta$ ;\*)=20 $\theta$ +15 for  $1/2 \le \theta \le 1$ . Node 11 is not fathomed. See Figure 11.

Node 12. LP is infeasible. The dual extreme point is u=(5,0), v=(0) and the extreme ray is y=(1,0), z=(0). The critical value of  $\theta$  is  $(-y(b-\beta^{12})-ze)/yd=1$  Therefore  $UB^{12}(\theta) = -\infty$  for  $0 \le \theta \le 1$  and node 12 is fathomed.

Nodes 13-18 are all at the bottom level of the search tree. The solution for node 18, (1,1,0,1), has value 30 and is feasible for  $\theta \ge 3/4$ . The lower bound function may be improved by redefining  $LB(\theta)=30$  for  $3/4\le \theta \le 1$ .  $LB(\theta)$  now coincides with  $g(\theta)$  on  $0\le \theta \le 1$ . The algorithm terminates since the candidate list is empty.

The amount of extra computation required to solve (PIP), as compared to  $(P_0)$ , depends on the length of the interval of parameterization. When this interval is small, the burden imposed by parameterization may be slight or even negligible. When it is large, however, as illustrated in this example, the burden can be quite substantial.

# 7. Computational Results

The ideas presented above were tested by incorporating them into a branch-and-bound computer code [3]. The results for three test problems are presented in Table 1. In each run the direction vector d was taken as some percentage of the right-hand-side b. For example, if d=5%b, then (PIP) has right-hand-sides b+ $\theta$ (.05)b for  $0 \le \theta \le 1$ . The column headed "solutions" gives the number of optimal solutions found, or equivalently the number of steps of the g( $\theta$ ) function. "Heuristic" is the number of (evenly spaced)  $\theta$  values for which the heuristic is applied at Step 7. The problems are of the capital budgeting type and the heuristic employed is that of Toyoda [11]. "Pivots" is the total number of linear programming pivots and "time" is the total solution time in seconds on an IBM 370/168.

These results illustrate quite clearly how the computational burden increases as the interval of parameterization is lengthened. In order to facilitate comparison with our results by other researchers we have included the data for the  $5\times30$  problem as Table 2 and the corresponding  $g(\theta)$  function for a 10% increase in b as Table 3.

Table 1. Computational Results for three test problems.
