The Evolving Market for Catastrophic Event Risk

Kenneth A. Froot

NBER Working Paper No. 7287

August 1999

JEL No. G22

ABSTRACT

This paper discusses the recent changes in the market for catastrophe risk. These risks have traditionally been distributed through the insurance and reinsurance systems. However, because insurance companies tend to share relatively small amounts of their cat exposures and because insurance companies' capital is threatened by large event, these risks are now being shared partly through the capital markets. In looking to likely future developments, the paper enumerates five key ingredients that successfully structured cat instruments are likely to share: retentions should be substantial; layers of protection should not be too high; dollar amounts of risk transfer should not be too small; loss triggers should be beyond prudent control; and loss triggers should be symmetrically transparent.

Executive Summary

- Catastrophe risks have traditionally been distributed through the insurance and reinsurance systems. Insurance companies cumulate the catastrophe risk of individual entities and redistribute the risk to the global reinsurance industry, and, ultimately, to shareholders.
- Insurance companies retain large exposures to catastrophe events. For cat events generating an \$8 billion industry loss – one half the losses from Hurricane Andrew – only 20 percent of losses are covered by reinsurance. This means that insurance companies are using their own equity to finance this risk, an inefficient way to use capital.
- Because of the inadequacy of reinsurance capacity and the potentially enormous size of catastrophe risks, insurance companies and corporations have sought to spread these risks to the capital markets.
- The development of computer modeling of natural perils and the growing knowledge of cat risk among institutional investors is increasing market capacity.
- Evidence of the improving efficiency of the market can be observed in the decline in price for catastrophe reinsurance over the past four years. The price decline only partly explained by the absence of major cat events; much of it is permanent.
- Further progress can be seen in the development of capital market instruments to address cat event risk. In 1997, the first large and truly successful “cat” bonds were issued.
- Looking to the future, successfully structured cat bonds issues are likely to require five key ingredients:
 1. Retentions should be substantial. This is partly for institutional reasons. Bond markets prefer issues where there is a low probability of loss of principal, and high retentions mean that the probability of loss will be low.
 2. Layers of protection should not be too high. High levels of protection involve extremely low probabilities of loss. For example, earthquakes in the 8+ range on the Richter scale may only occur in 1000 years. Very low probabilities mean that the bonds will be priced low and these prices cannot justify the expense load of underwriting cat bond issues.
 3. Dollar amounts of risk transfer should not be too small. A large portion of the issuance costs of bonds are fixed and need to be spread over a large base.
 4. Loss triggers should be beyond cedent control. Cat event risks cannot generally be controlled by cedent insurers. However, aggressive mitigation and claims management may be reduced for losses beyond the trigger. This problem can be contained by using industry-wide loss triggers, such as the Guy Carpenter Catastrophe Index.
 5. Loss triggers should be symmetrically transparent. Cedent companies normally will know more about the risks they face than investors. The use of industry loss triggers can reduce this problem.
- Additional investment groups are expected to take on insurance risk. The first group is traditional reinsurers, who are raising equity from investors to write insurance risks. A second group is also raising capital, but is placing the risk in tax advantaged markets such as Bermuda. Finally, a third group is expected to emerge looking more like mutual funds, where investors own shares of the fund assets.
- The new sources of capital will tend to undercut the reinsurance pricing cycle. Large price movements will attract capital to these markets. This increased supply will minimize the upward movement in prices that would normally occur following a cycle turn.

I. Introduction

In the last year, the market for catastrophic event risk has witnessed important change. The first large and truly successful “cat” bonds have been issued. New exchanges have opened and exchanged contracts have been created. Indexes of cat losses have been introduced. The array of products confronting issuers and investors has widened substantially.

This paper provides a brief overview of these changes. It also takes a functional approach to diagnosing the problems in the market for cat event risk in order to understand how change going forward is likely to occur. Finally, it provides information to companies looking to assess whether these new markets are useful for solving their problems.

II. Background

The distribution of catastrophe risk is highly unfavorable without insurance and reinsurance. Individual households and companies are highly exposed to their own property damage and because they are not exposed to others’ property damage, these entities are not rewarded with a financial gain if no cats occur. Households and corporations dislike this situation; they face large potential downside from cats that affect them, yet receive no upside when no cats occur.

Insurance, reinsurance, and the capital markets provide an obvious redistribution mechanism whereby those who are exposed can protect themselves against cat loss. Households and companies are risk averse; therefore they will pay more than actuarial losses for insurance. This demand translates then into upside for others. When there are no catastrophes, each entity’s premiums are redistributed to others in the form of financial gains.

A. Inefficient catastrophe risk distribution

Clearly, a catastrophe risk distribution mechanism exists for cat risk. But how well has it functioned historically? The answer is not particularly well. Many entities, particularly businesses, have large assets that remain highly exposed to cat risk. This is because large-size insurance and reinsurance policies are difficult and costly to obtain. Indeed, even insurance companies that underwrite policies affected by cat events have experienced difficulty transferring substantial quantities of cat risk to reinsurers.

To demonstrate this, Figure 1 shows the fraction of cat losses that insurers protect through reinsurance, averaged across insurers. It shows that the fraction of protection is high for relatively small cat losses, but low for moderate sized cat events. For example, for cat events generating an \$8 billion industry loss, only about 20% of marginal insurer losses would have been covered by reinsurance as of 1994.^{1,2}

A well-working risk distribution mechanism would have an insurer, like any other company, ceding most of its own cat exposure. By self-insuring, companies are requiring their equity holders implicitly to provide the insurance.³ After all, equity returns are the first to suffer

¹ Figure 1 actually overstates the fraction of losses covered, since it averages across only those insurers that purchase some amount of reinsurance. If insurers that purchase no reinsurance were included, the fraction shown in Figure 1 would decline.

² A cat event that generates a loss of \$8 billion (1996 dollars) is not extremely unlikely, with a probability of exceedence of approximately 15 percent.

³ Of course, to the extent that the firm has insufficient capital / surplus to sustain a loss, equity holders share the risk with other claimants of the firm: bondholders, trade creditors, and policy holders.

when there is a cat-event loss. But self-insurance is likely to be inefficient for several reasons.

First, equity investors typically expect high average returns. This is largely because equities have large amounts of undiversifiable risk – they move strongly with the entire stock market, and the stock market is volatile. By contrast, catastrophe risks can, for all intents and purposes, be fully diversified when embedded in standard portfolios of stocks and bonds.⁴ As a result, both the returns and risk associated with cat exposures are likely to be lower than those associated with equities. Equity investors would prefer a pure high-risk / high-return product, and would rather not have the “reward dilution” associated with cat exposures.

Second, equity investors typically expect a long-lived, complex risk. (Even if their trading horizons are short, equity investors know that the current stock price telescopes back both short-horizon as well as long-horizon perceptions about the firm’s prospects.) Equity risks are therefore not targeted to precise events over precise periods of time; rather, they tend to evolve over time, their nature at least partially opaque.

Cat risks, by contrast, can be thought of as *event* risks. Writers of cat reinsurance receive a predetermined premium in exchange for protection against a prespecified event, with a predetermined maximum loss over a predetermined period of time. Whether imbedded in a traditional reinsurance contract or in a cutting-edge cat bond, the event’s nature is clearly defined. Even though the probability of the event may be uncertain, the risk doesn’t evolve much and the scenarios that produce losses and gains are fairly transparent. The event risk is studied more when it has to stand alone. Modeling firms attempt to quantify the likelihood and severity of dollar damages, and the models are then reviewed by specialists and investors. Much more light is cast on the risk than if it remained – unquantified and amorphous – embedded in equity.

Event-risk exposures’ clarity and specificity make it easy to separate cat risks from other risks imbedded in equity such as: management risk, firm-specific product risk, firm-specific cost risk, industry-specific product risk, industry-specific cost risk, general macroeconomic risk, etc. *It is fundamentally inefficient to take a clearly-defined event risk and imbed it into an ambiguous, multipurpose instrument like equity.*

Closed-end mutual funds are a good example of the costs of clouding up clearly-defined risks. Closed-end funds invest in publicly traded securities and then sell stakes in their portfolio to shareholders, much like open-end mutual funds do. The difference is that open-end funds allow shareholders to sell their shares back to the fund at a price dictated by the net asset value of the portfolio. Closed-end funds do not automatically buy and sell their shares; rather, a shareholder wishing to sell must find another investor who wishes to purchase the shares. And the price of the closed-end-fund shares, like the price of most traded stocks, must find its own value in the marketplace in accord with supply and demand.

Now there is a puzzle associated with closed-end fund shares: their prices are, on average, considerably below the net asset values of the shares they own. This cannot happen with open-ended fund shares. Closed-end share discounts average about 10%-20%, and are pervasive across funds. Why is there such a discount? The reason is that shareholders can’t observe or control what managers do next with the portfolio. If managers make bad trades, an investor would prefer to liquidate the portfolio now at its net asset value. Investors will pay a lower price for a manager-controlled portfolio of stocks – i.e, they demand a higher

⁴ For discussion regarding the lack of correlation of cat risks with traditional asset classes, see Kenneth A. Froot, Brian Murphy, Aaron Stern, Steven Usher, “The Emerging Asset Class: Insurance Risk,” Guy Carpenter & Co., Special Report, July 1995.

return on their capital when its control is given to a manager. The lack of transparency, clarity, and control associated with managerial discretion creates these higher capital costs. Closed-end funds are therefore expected to pay average returns in excess of what the underlying assets earn.

In this example, the underlying stocks in closed-end fund portfolios are analogous to clearly-defined cat risks: the risks they represent are transparent and specific. Closed-end fund equity is analogous to other companies' equity. Just as closed-end funds could raise their market value by selling off a portion of their portfolios and returning the cash to investors, companies with cat risk could maximize their value by taking the cat risk out of their equity and letting it trade on a separate market for cat event risk.

Not incidentally, a direct implication of the closed-end fund argument is that reinsurers may be inefficiently funded, and therefore that their reinsurance is expensive. Reinsurers underwrite pools of cat risk retaining most, effectively self-insuring through their equity holders. Pooling helps diversify the cat risk, but it does not give equity investors the high-octane risk and reward they seek, nor does it retain the clarity of the component event risks. Reinsurers who are currently struggling with the need to earn "equity-like" returns on their underwriting activities increasingly have too much equity and too little event risk protection to be fully efficient.

B. Why is cat risk distributed inefficiently?

The above arguments suggest cat-event risk sharing is currently both poor and inefficient. Why is this the present state of affairs? One reason is that technology and computer modeling of natural perils have only recently reached the point where the risks can be cheaply and objectively clarified. If little can be said objectively about the risk of an event, then risk sharing is less likely to occur, as buyers (that is, assumers) of the risk worry that they will be sheep and that sellers will be wolves. Cat risk tends to accumulate, and firms self-insure.

A second but related reason for the present state of affairs is that it is costly to back cat protection with capital. These "frictional" costs can add up to be a significant portion of premium. For example, suppose that financial technology is such that the costs of assembling a pool of funds from investors is 2% of the size of the pool. These "deadweight" costs of creating the pool can be large relative to the premium the pool can be used to generate. Thus, these costs make it "expensive" to provide protection for unlikely events. Of course, as financial technology improves so that it is cheaper to assemble the pool, the inefficiency diminishes.

Another reason the institutional arrangement may be inefficient is that the lack of objective information acts as a kind of barrier to entry. When objective information is costly to assemble, a greater investment is required to get into the underwriting business. Indeed, when objective information is in short supply, markets tend to be organized around relationships and reputation. By contrast, when objective information is plentiful, markets tend to be organized around transactions, with the players being more interchangeable. Because newcomers are discouraged from entering the market, the incumbents who specialize in underwriting cat risks, such as cat-risk reinsurers, can more easily charge high prices.

While today's markets are inefficient, competition and innovation are making them less so. It is therefore useful to understand where this greater efficiency will take us. As we have argued, we are likely to see that companies will maximize their market values best by ceding cat event risks into a cat event risk market and non-specific risks into the equity market. As Adam Smith saw centuries ago, specialization is the key to greater efficiency.

C. Evidence of improving efficiency

The cat risk distribution has been, and is still, inefficient. But our real emphasis is on the forces of, and evidence for, *change*. It is, of course, hard to measure how much efficiency has increased recently. However, there is considerable evidence that is consistent with recent improvement.

Most important is the evidence that the price of cat-event protection has fallen for the past four years. Figure 2 shows the average rates-on-line (ROL) on catastrophe excess-of-loss contracts for the decade from 1989 to 1998.^{5,6} Rate on line increased substantially following Hurricane Andrew in 1992. By 1993, ROLs averaged 2.5 times 1989 levels. Then, beginning in 1993, rates began to fall. ROL fell steadily from 1994 through 1998. As indicated on Figure 2, the ROL of today's market is at approximately the same level as in the late 1980s - before the impact of Hurricane Andrew and the Northridge earthquake.

However, it is important to remember that rate-on-line can be a misleading measure of the price of reinsurance. For example, suppose rate-on-line stays constant, but the retention (i.e., deductible) specified in the reinsurance contract falls. All else equal, this means the reinsurance is invoked more frequently. In effect, more protection has been purchased for the same overall cost, so the price "per unit" has actually fallen.

In addition to showing ROL, Figure 2 also provides an improved measure of price. The "price index", compiled and calculated by Guy Carpenter & Company Inc., adjusts ROL for changes in retention. Clearly the price index shows an *even more dramatic change* in price, upwards in the immediate aftermath of Hurricane Andrew, then downwards thereafter. Thus, the basic impression that comes out of Figure 2 is not due to mismeasurement - prices did indeed fluctuate substantially in the 1990s, as it first appears.

Capacity fluctuations are one explanation for these price changes. Prices rose in the early 1990s because capacity was reduced (i.e., the supply of reinsurance fell as a result of catastrophe losses from events). Subsequently, there were few large cats, which lead to a regeneration of capacity. Of course, aficionados will point out this "supply-side" story is not the only possibility - that there is a second explanation, i.e., price changes might also have been *demand* driven. That is, demand for reinsurance increased following the occurrence of Andrew and Northridge, and then fell with the paucity of additional cats. It is not immediately clear which force - supply or demand - was more important in generating the prices in Figure 2.

However, we can distinguish between these two explanations by examining the two curves in Figure 2 more carefully. The fact that the price index amplifies the movements in ROL implies that *less* reinsurance was purchased as prices rose and *more* was purchased later when prices fell. This pattern is not consistent with a demand effect, which would say that *more* (less) reinsurance would be purchased during times of increasing (decreasing) prices. Only supply shifts could generate the price and quantity patterns we observe.

In other words, over the last four years, the price of reinsurance has fallen, while the quantity of reinsurance purchases has risen. (Note that the quantity purchased has increased particularly strongly in the last year of the sample. This suggests that, for the years

⁵ Rate-on-Line is the ratio of premium to limit (i.e., maximum possible loss under the contract), averaged across contracts.

⁶ Data has been compiled by Guy Carpenter & Company, Inc. using a sample of reinsurance contracts it brokered.

immediately preceding 1997, prices declined *less* rapidly than suggested by ROL.) Only changes in supply could account for this pattern. And increases in supply come from greater competition and efficiency in production. In some sense, the reinsurance market is like the computer chip market – increasing efficiency allows prices to decrease even while quantities soar.

There is also evidence that the improved efficiency in the provision of reinsurance has affected reinsurance buying patterns of insurers'. Figure 1 shows that, over time, insurers have come to purchase greater amounts of coverage for mid- and large-size events. By 1994, the fraction of large losses being reinsured may be low, but is nevertheless much higher than before. Greater competition in the reinsurance market seems to have improved the sharing of cat event risk.

III. Financial Innovations

Financial innovation permits greater competition among capital suppliers. In the last few years, clear and well-defined cat event risks have been brought directly to investors for the first time. This direct sourcing of investor capital can improve efficiency by removing layers of management, separating cat risk from equity risk, and improving the information with which those who bear the cat risk have to work. In this section, we discuss several of the mechanisms used thus far to securitize cat event risk.

Table 1 lists most of the important securitized cat event risk transactions to date. As these are the first transactions to occur, there is as yet little standardization. Each transaction is different and challenging in its own way. The purpose in this section, however, is *not* to exhume the fine details of each. Examples are used from Table 1, but the goal is to convey a broad characterization of the securities and the way they work. With an emphasis on the functional characteristics of these innovations it is possible to think about the opportunities and limitations for new, as-yet-to-be-completed transactions.

There are two basic methods of delivering cat-event risk directly to investors: financing transactions and risk-transfer transactions. Financing transactions are those that, upon the occurrence of an event, exchange funds from investors with securities. In a financing transaction, the securities require the insured to repay investors over time, and the exchange of securities for cash is done at fair value at the time of the exchange. Thus, when the cat event occurs, the investor loses no money: \$100 worth of securities is received in return for \$100 in cash. The main risk faced by investors, therefore, is that they are obliged to come up with the cash quickly. A standard credit facility with a bank is an example of a pure financing transaction (however, drawdown on a credit facility is generally not tied to cat events).

Risk transfer transactions are different. Here the investor *loses* when the cat event occurs. Specifically, the investor purchases securities with pre-determined event-linked payments. This exchange occurs before the cat event. If and when a cat event occurs, investors receive less-than-full repayment. In this way, investors share in the event-linked loss of the insured. If no event occurs, investors share the insured's upside. With risk transfer, the insured company and its stockholders bear less cat event risk than they otherwise would. Reinsurance and insurance are examples of more or less risk-transfer arrangements, though they are not capital market instruments and they sometimes contain financing elements.

Risk transfer solutions are likely to be a richer area for innovation than risk financing transactions. Better risk sharing – which is critical – can be accomplished only through better risk transfer. On the other hand, contingent risk financing can be accomplished in a number of ways. For example, the ability to perform straight financing operations (through

debt, equity, or any other instrument) whenever desired obviates any strong need for contingent financing. Moreover, financing methods for general-purpose contingencies – such as bank credit facilities – are close substitutes and are widely available.

A. Financing cat event risk: Contingent Surplus Notes

In terms of financing linked to cat events, there are two main prototypes. The first is an event-linked issuance of debt. Insurers who have done this have typically issued surplus notes. Surplus notes are basically debt instruments, which for regulatory purposes may be treated as capital. In spite of their status as statutory surplus, surplus notes oblige the issuer to repay the funds on a fixed schedule. As a result, these transactions cannot transfer risk; cat-event losses are still borne by the company and its equity holders. The contingent part of contingent surplus notes is that the investors agree to accept the surplus notes not when the deal is struck, but when a particular event, such as a cat event occurs.

Table 2 shows a list of surplus note issues. Most of these issues are straight surplus notes: insurers borrowing funds directly which they then use as statutory capital. Investors receive repayment in the form of interest and principal, or, if the issue is structured as a preferred stock, in the form of dividends and principal.

Only a few companies have issued contingent surplus notes: Nationwide, Hannover Re, and Arkwright. In these transactions, investors place funds into a safe account and receive account-ownership certificates. Initially, the account holds US treasury bills. Interest on the Treasuries passes through to investors, so it is as though investors are holding safe government securities. However, there is the following additional wrinkle: under a set of pre-established conditions, the insurer (or reinsurer) can withdraw the liquid Treasury securities from the account and replace them with its own surplus notes. At that point, investors would receive interest and principal from the issuer, so they would bear the credit risk associated with potential issuer default. Investors are compensated in two ways for this added risk: first, the surplus notes pay a higher coupon than US Treasuries; and second, starting at the time the safe account is established, the issuer pays investors a premium for the right to “put” its own surplus notes into the account and withdraw the funds. In a pure financing transaction, the higher coupon on the surplus note would by itself be sufficient to compensate investors for the possibility of issuer default. In that case the “put” premium would be compensation only for liquidity – i.e., for knowing that the facility is there when it is needed.

B. Financing cat event risk: Contingent Equity

An alternative to contingent debt is, naturally, contingent equity. The setup is similar: the insurer pays a fee to investors for the right to issue equity later in return for cash. When issued, the equity would fetch the going market price, so that investors would receive \$100 worth of stock for \$100 of cash. What makes contingent equity different from a vanilla equity issue is the modifier ‘contingent’: the trigger for the issue is cat-related event losses incurred. As long as investors receive the stock issue at the then-fair price, contingent equity is a pure financing vehicle. While investors do not lose money when the equity is “put,” they require nevertheless a payment in return for the contingency. This payment can be thought of as compensation for the investor remaining sufficiently liquid to purchase the put equity on demand.

In practice, the transactions involving contingent equity have been slightly more complex. Partly as a result, they may include elements of risk transfer as well as risk financing. A good example of a contingent equity transaction was a \$100 million issue by LaSalle Re. LaSalle paid approximately \$2.4 million per year to investors for the right to sell them \$100 million in preferred shares. LaSalle was entitled to exercise this right if its losses from a single cat

event exceeded \$200 million, or if its aggregate losses for any year exceeded \$250 million. The preferred shares paid dividends of LIBOR plus a spread. The spread was set according to a predetermined schedule – higher if LaSalle’s credit rating was low at the time of the issue and lower if LaSalle’s credit rating was high at the time of the issue. This helped insure that investors would suffer only minimally if cat losses reduced LaSalle’s creditworthiness. Once issued, the preferred shares were convertible to LaSalle common equity. The conversion was to be effected at the 30-day average stock price prior to conversion.

In order to be predominantly a financing vehicle this structure attempts to minimize any risk transfer component. The dividends on the preferred stock are set according to the credit rating at the time of the contingent issue. And the preferred stock is converted to common at the current fair price. Thus, while cat losses may trigger LaSalle’s need for financing, they are unlikely to impose a loss on investors. Just as in the contingent surplus note transactions, investors need only supply the cash to buy fairly priced securities in the aftermath of cat event losses.

Thus far, there have been relatively few contingent risk financing transactions – debt or equity – even in the presence of a large market in finite reinsurance. There are apparently too many close substitutes available at competitive cost. Reliable financing in the aftermath of a cat event can be found either through an on-the-spot *ex post* issue of a debt or equity, or through a prearranged *ex ante* contract that allows draw down at any time. Indeed, the distinction between even the *ex post* and *ex ante* solutions is blurred by conventions such as shelf registration, which allows for very rapid access to commercial paper or other medium funds.

C. Transferring cat event risk: Act-of-God Bonds

In most instances, however, *financing* cat event risk is not enough. Suppose, for example, a cat loss occurs which is larger than the going-concern value of an insurer. Could the insurer arrange a pure financing transaction in anticipation of that loss? The answer is no: investors would not provide contingent financing because their securities would be dead-on-arrival, worth less than their purchase price. The going-concern value would be lost, if the insurer had to rely only on risk financing. Risk transfer, however, can preserve the going-concern value. By ensuring that the firm shares its cat-event exposures, the firm’s future can be sustained.

Standard insurance and reinsurance contracts are reasonably elegant techniques for transfer of cat risk. But like any real-world technique, they are not perfect. First, and foremost, the cedent bears the credit risk of the insurance or reinsurance counterparty. There is usually no iron-clad “quadruple A” guarantee that the insurance protection will be there when the insured becomes entitled to it. The problem can be diminished – though not eliminated – by buying reinsurance from a collection of reinsurers. Moreover, dividing the transaction up into pieces can be costly.

Second, in the past, cat reinsurance agreements included the tacit understanding that there was a financing element to the transaction. The traditional reinsurance transaction was in fact not pure risk transfer, and this was a shortcoming. After a cedent declared a loss under the contract and the loss was paid, it was assumed that the cedent would continue buying reinsurance from the same provider, and that it would voluntarily do so at a higher price. The higher price didn’t so much reflect an increase in the probability of loss as it provided the reinsurer the opportunity to “make back” paid losses. Pure risk transfer transactions, by contrast, are memoryless – their terms are set according to the risk at hand, and are otherwise independent of previous outcomes. Of course, there is nothing about the reinsurance contract itself that requires consideration be paid for past claims. So this

“shortcoming” is more a matter of industry culture. And, perhaps as a consequence, this aspect of reinsurance is likely to change going forward.

“Cat” bonds perform a risk transfer function similar to that of insurance and reinsurance. They also avoid the shortcomings mentioned above. With a cat bond, investors place cash into a safe account from which they receive interest. This account is normally structured as a safe trust. The proceeds of the account are available to the cedent only if a cat-event loss occurs. In return for this benefit, the cedent pays into the account a premium, which is transferred (in addition to interest) directly to investors. If there is no event loss, the safe account remains just that – safe. After paying interest and premium to investors for a prespecified period of time (usually from one to three years), the full principal is returned to investors. However, should there be an event loss, the investor will receive only that portion of principal and interest that is left after paying the cedent’s event losses.

The first thing to note about this structure is that it resolves the shortcomings of traditional insurance and reinsurance contracts. The cedent bears no credit risk – the funds are remote from any other claims or possible uses while in the safe account; they are there for the sole purpose of paying cedent event losses in case there is an event. Also, because the cat bond is purchased in the capital markets, it is a transaction with no judgements about past events. There is no relationship between investors and the insured to manage. Investors cannot extract a ‘repayment’ for the losses of prior cat bond investors. Prior losses may raise the perception of future losses, but in no sense would the cedent in a transaction be paying back the investors who lost last time around.

The second thing to note about cat bonds is that they may have an unexpected and surprisingly widespread positive side effect: improving the general clarity of corporate bond analyses and ratings. With cat models serving as reference points, a given cat bond will have a certain likelihood of paying in full and an average ‘recovery’ payment when payment isn’t full. The promised yield on the bond will depend on both. That is, investors require a higher yield to compensate either for a lower probability of full repayment or for a lower recovery amount, given default. The rating, too, will need to take both probability and recovery into account. Figure 3 shows how Fitch summarizes the relationship between rating, probability, and recovery. Each “iso-rating curve” in the figure is generated by a set of probabilities and recovery rates. The higher the probability of full repayment, the lower the recovery rate must be if the same rating level is to be maintained.⁷

In the past, rating agencies have never been precise about the exact combinations of probability and recovery that result in a given rating for any kind of bond. In fact, some rating agencies (e.g., Standard & Poor’s) have maintained that they evaluate *only* probabilities, and not at all net recovery, when assigning ratings. In the context of cat, this makes little sense. And, when one thinks about it, makes little sense in *any* context. Recovery rates clearly affect investor risk and reward, so they should also affect ratings. It seems that precision modeling of cat events (however rudimentary it may be) has generated additional clarity on what ratings mean. Over time this will lead to improvements in the transparency of the ratings process.

The third thing to note about in the cat-bond approach is that it, too, has shortcomings. Clearly, it is costly to set aside enough in an account large enough to pay the largest possible loss under the cedent’s contract, no matter how unlikely that loss is. To see this, consider the fact that approximately \$186 billion in capital and surplus backs all worldwide property/casualty reinsurance contracts issued by the world’s top 100 reinsurers.⁸ If these

⁷ We thank David Mordecai of Fitch, IBCA for providing this figure and the underlying analysis.

⁸ Figure for 1996 from Standard & Poor’s.

traditional contracts were alternatively structured as cat bonds, they would require the total *sum of all the limits* – nearly one *trillion* in capital. While it is not unthinkable that such a large sum of money could be raised, it is certainly a very large amount – on the order of the amount tied up in securitized mortgages. It would seem inefficient to raise the maximum potential loss for each and every risk – especially those risks for which the probability of loss is tiny. To the extent that the losses are unlikely and uncorrelated, it becomes more efficient to pool the risks together in a fund. That looks more like the traditional solution, reinsurance.

To demonstrate in greater detail how a cat bond works, it is useful to examine the 1997 USAA transaction – the first large-scale cat risk transfer through securities.⁹ In this case the safe account was a trust, administered by an off shore special purpose reinsurer (SPR) called “Residential Re.” The SPR had no business purpose other than to sell a one-year \$400 million reinsurance contract to USAA and to issue \$400 million in risk-transfer securities to fully collateralize that reinsurance.¹⁰ The proceeds of the issuance were held in a trust and invested in highly rated, short-term investments such as commercial paper. In the event of a catastrophe, the trustee would have sold the investments to cover 80% of USAA’s losses in excess of \$1 billion (until the \$400 million is exhausted). In return for this reinsurance, Residential Re received a premium from USAA of 600 basis points (\$24 million). The premium, along with virtually all of the interest on the commercial paper, went directly to investors, regardless of whether USAA experienced a loss.

To fund the reinsurance, Residential Re issued securities of two types: principal variable and principal protected. If there was a loss, principal variable investors would have lost some or all of their initial investment. These notes paid interest at a rate of LIBOR plus 575 basis points (this is essentially interest plus the reinsurance premium of 600 basis points, less about 25 basis points for costs).¹¹ The principal protected securities would have had their principal repayment delayed for 10 years in the event of a loss, with a reduction in interest along the way. The principal protected securities paid LIBOR plus 273 basis points. Figure 4 and Table 3 provide additional details of the transaction structure.

D. Transferring cat event risk: Standardized Contracts

Cat event bonds are not the only vehicles for transferring risk. Swaps and forward contracts can be linked to cat losses in much the same way as can bonds. However, these “derivative” contracts have an important shortcoming that bonds do not share – credit risk. Much like traditional reinsurance contracts, the cedent has a claim only on a counterparty, not a safe account. So it isn’t surprising that securitized contracts which simulate insurance or reinsurance tend to be structured as bonds.¹²

However, full collateralization is not the only way to reduce credit risk. Exchanges can reduce credit risk by marking to market contract frequently and by standing in between buyer and seller to guarantee contract performance. With this problem solved, the exchanges are

⁹ This section draws on Kenneth A. Froot and Mark Seasholes, “USAA: Catastrophe Risk Financing” Harvard Business School, case no. N9-278-007, July 1997.

¹⁰ The reinsurance contract was 80% of the layer of losses in the range of \$500 million in excess of \$1 billion, deriving from a single hurricane. The structure of the Residential Re reinsurance contract is similar to that of standard reinsurance contracts. The main differences are that only one cat-event loss can be claimed and that there are no reinstatement features.

¹¹ To compare these percentages with actuarial losses, the risk of USAA sustaining losses in excess of \$1 billion is somewhat less than 100 basis points.

¹² In addition to credit risk issues, derivative contracts such as swaps and forwards run the risk of being classified as “insurance” contracts by insurance commissioners. “Insurance” contracts are highly regulated and are not considered appropriate for investors.

positioned to offer another benefit: the liquidity associated with trading standardized instruments. This is a benefit indeed, as high volume, low cost trading in standardized cat-event linked contracts would seem an effective means of improving risk sharing.

To achieve standardization, exchanges have linked cat-event futures and options contracts to aggregated measures of cat losses. The payoffs on these contracts are therefore tied to industry, rather than individual, losses. The Chicago Board of Trade is trading futures and options linked to the Property Claims Service (PCS) index and the Bermuda Commodities Exchange is trading contracts linked to Guy Carpenter Catastrophe Index (GCCCI).¹³ Table 4 provides data on the exchange-traded contracts.

Standardized contracts have several important features worth noting. First, because of the aggregated nature of the indexes, they are not designed to indemnify – i.e., to match the losses of – any particular entity. As a result, any given insurer, reinsurer, or corporation ceding risk through these contracts will experience ‘basis risk’ – deviations between cedent losses and those paid by the contract. Sometimes when the cedent experiences a loss, the contract will not pay as much as the loss; sometimes it will pay more. All else equal, this makes aggregate standardized contracts less attractive.

But the size of the basis risk varies considerably. It depends in part on the nature of the insurance portfolio being hedged and the choice of index. Clearly, lumpy portfolios that contain a few large industrial assets will not show losses that are tightly linked to total cat losses across a large area like a state or region. Portfolios that contain homes evenly dispersed across an area will perform more like the area aggregate. Furthermore, most portfolio concentrations vary geographically. That is, market share changes considerably with location for insurance carriers. Indeed, market share varies not only across regions and states, but counties and zip codes. Thus, the greater geographic disaggregation of the GCCCI index proves valuable for many portfolios.

Second, while standardized contracts generate basis risk for hedgers, they simplify life for investors. Imagine if investors were to buy diversified portfolios of cat event risks by purchasing individual bonds. One at a time, investors would have to evaluate facilities such as Residential Re and the underlying risks of companies such as USAA. This is hard work, and, even worse, redundant work. Each investor would need to separately analyze each individual risk. It is far more efficient for these risks to be bundled first – into something that looks like an aggregated index – before being marketed to investors. That way each investor needs to understand only one kind of contract. The implication is that standardization makes it far less costly to distribute cat-event risks widely.

Along these lines, it is interesting to note that, in 1998, USAA placed a layer of reinsurance through a securitized transaction that was equivalent to the layer placed in 1997 by Residential Re. The risks of the securities were essentially the same. Yet the pricing of the 1998 bonds, issued by Residential Re II, was considerably lower. On a comparable basis, the 1998 bonds provided a one-year return over LIBOR of 416 basis points, compared with 576 basis points for the 1997 bonds. This decline in return partly represents savings by investors and intermediaries. They needed to expend far less time and energy understanding the transaction, having studied the same underlying package of risks one year earlier.

Third, it is worth distinguishing the role of standardization from that of the exchanges. Strictly speaking, standardization does not require an exchange, or for that matter, even securities, to work. Traditional reinsurance contracts can (and are) standardized by adding triggers responsive to aggregated industry losses. However, the *value* of standardization is

¹³ See the discussion below for more details on these indexes.

greater the more liquid are the underlying contracts. With greater liquidity, standardized contracts can be sold and traded more widely. As with any other standard, the value is that *everyone* is on it.

IV. The five key ingredients for a successful cat bond issue

When are cat bonds and other securitized forms of risk financing likely to work best? Of the structures we have seen so far – contingent surplus notes, contingent equity puts, and cat bonds – the bonds are the purest. They provide true risk transfer, which unlike pure financing alternatives, does not merely prolong the day of reckoning. They avoid use of all-purpose equity financing, even on a contingent basis. They focus in on the cat event risks at hand, promoting greater transparency, and helping reduce the costs of capital. They provide large capacity with zero-credit risk protection funded by competitive capital markets.

However, as we have noted, cat bonds have weaknesses, and may not be appropriate in many circumstances. When, therefore, are cat bonds likely to be economically superior to traditional reinsurance? What conditions need to be present in order for cat bonds to be the preferred choice? In this section we try to answer these questions by providing a list of ingredients – preconditions, really – that are likely to make cat bonds the risk-transfer mechanism of choice.

Ingredient #1: The retention should be substantial

Like traditional reinsurance, cat bonds need to cut possible losses into layers, so that each contract has an associated limit, or maximum possible loss. Low layers are those that are impacted frequently, as many cat events generate at least a low loss level. High layers – like the USAA example above – are those that are impacted relatively infrequently, as few cat event losses breach the contract retention (i.e., deductible). Most of the cat bond transactions in Table 2 have low probability of loss, and therefore translate into relatively high reinsurance layers. Indeed, the highest likelihood of loss among all the transactions is only 25%, and the most have been completed at probability of loss closer to 1% – a one-in-a-hundred likelihood of loss.

There are several factors that make this the case. First, there are institutional issues associated with fixed-income investing that bias choice toward higher layers. This is because many institutional fixed-income investors are restricted in their mandates: they must hold predominantly bonds that are rated; and they must hold bonds that have minimum credit ratings.¹⁴ The demand for higher-rated bonds is greater than for “junk” debt, which is deemed less than investment grade. In assigning a rating for bonds, credit-rating companies examine the probability of less-than-full-repayment of principal and interest. A bond with an actuarial risk of loss of about 2% or greater is likely to generate a rating below investment grade, reducing the number and types of investors who can buy it.

Of course, with a little financial engineering it is always possible to satisfy the rating agencies, improving the rating on relatively low layer protection. The most common method is called “principal protection”, which was used for the USAA Class A-1 notes. Under principal protection, some of the money raised from investors is never put at risk. Instead it is used to purchase long-term zero-coupon US treasuries at a deep discount. Since these securities will eventually pay their principal with certainty, cat bonds can be designed to pay back their principal with certainty too. If there is a cat event, investors lose money because they have to wait a relatively long time to get their principal back, and along the way interest payments

¹⁴ Bond ratings are promulgated by firms such as Moody’s, Standard and Poor’s, Fitch, etc.

are less than market rates. Using this feature, the Residential Re Class A-1 notes received the highest rating, AAA, while the Class A-2 notes were judged below investment grade at BB (see Table 3).

Naturally, there is a cost to this method: it waters down the cat event risk embedded in the bond. Principal protection requires that much more than a dollar is raised for every dollar of risk transfer. The extra money finances the purchase of the principal protection. For example, in the USAA transaction, \$164 million of Class A-1 notes were issued. But of this amount, only \$77 million went toward backing USAA's reinsurance. The rest went toward the purchase of zero-coupon US Treasuries. As a result, the Class A-1 notes paid only 273 basis points above LIBOR, compared with 575 basis points for the Class A-2s. If USAA had wanted to protect a lower layer, this ratio would have been worse, with risk transfer making up an even smaller fraction of the money raised. Since marketing, distribution (and sometimes fee) costs of an issue depend critically on the amount raised, the costs of a low-layer cat bond become problematic.

There is a second, entirely different reason why low layers are not naturally transferred through cat bonds. Among insurers, reinsurers, and capital market investors, none like to bear the first dollar of loss from a risk. As a result, most contracts stipulate a deductible or retention. The reason is to give high-powered incentives to the original owner of the cat risk. If a loss is declared, the owner pays the first dollars. This encourages good cedent behavior – better risk mitigation, loss-evaluation monitoring, etc. It also protects risk writers against private information cedents may have about their risk. The lower the layer, the worse the pool of cedents to come forward. Cedents who privately know the risk is bad are the ones who most want a low deductible.

These issues – formally referred to as moral hazard and adverse selection – are particularly important for cat bonds because the capital markets are at arm's length from the cedent. Traditional insurers and reinsurance methods bring the risk writer much closer. This is accomplished through on-going information conveyed by brokers, by relationships and by greater oversight and control over the cedent's risk-assumption process.

Over time, as arms-length disclosure of information improves, lower layer cat bonds may become more common. But as we discuss in Ingredients 4 and 5 below, techniques for managing moral hazard and adverse selection are crucial, and disproportionately so for lower layers.

The final reason that layers are likely to be high has to do with reinsurance pricing. So far, cat bond returns have more or less mirrored those of the reinsurance market. This is shown in Figure 5, which compares the pricing of cat bonds with traditional reinsurance contracts and options traded on the CBOT.¹⁵ And the pricing in the reinsurance market has been the most attractive in the highest layers. While this is apparent in Figure 5, it is clearly seen in Figure 6, which depicts the historical pricing of lower versus higher layers. Basically, large cat risks are the risks most destructive to insurers and reinsurers because they create a large need for additional capital. The return for providing this additional capital is thus most generous relative to the risk. Thus, it is perhaps not surprising that cat bonds have been targeted to compete with upper reinsurance layers.

Ingredient #2: The layer of protection shouldn't be too high

¹⁵ The options which appear to have the lowest prices remain relatively illiquid, and the returns which appear on the chart are reduced by transaction costs. Transaction costs are not included in the returns for cat bonds or reinsurance. Furthermore, the options are based on indexes of catastrophe losses, rather than net losses of individual insurers or reinsurers.

By itself, Ingredient #1 suggests that cat bonds are relatively more attractive as the layer becomes higher. This seems natural, given the limited capacity of traditional markets. Why not go out into the vast liquid capital markets for funding not just the next higher layer, but 3 or 4 layers beyond that? The answer, of course, is as layers become higher, risk transfer ultimately becomes less economical. There is a kind of Laffer curve at work. As the layer becomes too high, the probability of loss becomes too low. With very low probability of loss, the premium ought to be very small. But a small premium will be insufficient to afford the costs of establishing the safe account, the SPR, or marketing and distributing the cat bond. Moreover, the risks embedded in each bond – however small – are still unique. This forces investors to spend costly time understanding each risk. Very low risk cat bonds simply do not pay.

To get a sense for how low premiums can go to be economical, it is worth reckoning several of the more precise costs of a cat bond issue. First, the bankers will charge an underwriting fee. This could range between 50 to 250 basis points of the risk transfer amount, depending on the complexity of the structure and the quality of the underwriter. Given the state-specific regulatory nature of insurance, in some cases considerable travel expenses need to be paid by the cedent in addition to the fee.

Second, the legal costs of establishing the SPR and trust account are likely to be considerable. The legal work is complex because the SPR must have the ability to write insurance or reinsurance protection and issue claims that are designated as securities and *not* insurance or reinsurance policies. So it is not a standard (and less expensive) type of special purpose vehicle used to create asset- or mortgaged-backed securities. For cat bonds, the legal costs are likely to decline as the necessary legal expertise becomes more of a commodity. But currently this is not the case.

Third, clients incur the costs of producing information on the risk for investors and rating agencies. In particular, this involves fees to cat-risk modelers. This cost can vary tremendously, depending on the risk. But it also can be a substantial expense.

Fourth, there are fees to the rating agencies. These are still somewhat higher than fees on normal corporate or asset-backed securities because of cat bonds' still novel nature.

Fifth, there are various other costs associated with capitalizing the SPV, such as directors fees, licensing fees, claims and reserve consultant retainers, insurance fees, etc.

Taken together these costs can easily exceed 150 basis points on a \$100 million issue. To see what this does to the economics of a high layer cat bond, consider a bond with a 1 percent risk of loss. The actuarially-fair premium on such a bond would be 100 basis points. Even if investors were willing to buy bonds which paid only actuarially-fair rates, the bare minimum charge – premium plus issue costs to the cedent – for such a bond would be 250 basis points. The costs mean that cedents must pay is 2.5 times the minimum rate that investors are willing to receive.

It may be that cedent demand for protection is very great, but at some point the amount of protection gets too small relative to costs. At increasingly higher layers, the probabilities of impact fall. Clearly, at a layer so high as to have an actuarial risk of 1 basis point, the cedent costs would total 151 basis points – over 150 times as large! Unless the demand for protection is extremely inelastic, there is too little cedent protection in such a contract to make it worth the premium.

Ingredient #3: The dollar amount of risk transfer shouldn't be small

Because a large portion of the costs enumerated above are fixed, the 150 basis point threshold grows as the limit shrinks. A \$50 million issue would almost certainly require over 200 basis points in cost. And the \$400 million Residential Re risk transfer was done for at least 100 basis points. These costs must either be paid in addition to the premium, or must come out of investors' take. Clearly, small issues quickly become uneconomical.

The fixed-cost problem can be handled in part by using multi-year contracts. Although these are currently difficult to engineer, over time they will get easier. Today, participants are very unsure about how cat risks and the associated premiums should evolve over time. Cedents may need to pay a higher premium to successfully launch a multi-year issue.

The fixed-cost problem can also be reduced through an increase in the market-wide volume of cat bond issues. Legal, modeling, and investment banking fees are all prone to competition. A larger volume will support more competitors and allow fixed costs to be better amortized. Costs will therefore decline. But cat bond volume will probably never grow large in comparison with that of other fixed-income markets such as corporate debt, asset-backed bonds, or mortgage-backed securities. So, at least for now, the prospect of razor-thin margins is a dim one.

Finally, over-the-counter transactions can be a partial solution to the costs above. The required level of underwriting fees, legal expenses, and modeling work can be reduced in small private transactions. This creates greater leeway in finding cat bond possibilities. However, small private deals are by definition small and poorly advertised. The cost to a cheap distribution network can be that there is less competition among buyers.

Ingredient #4: The loss trigger should be beyond cedent control

Cedent control of the loss trigger is known as moral hazard. Moral hazard tends to keep markets from developing. No one will come to trade when the outcome of a contract can be determined by the entity on the opposite side of the trade. In most insurance-market instances, however, control is partial and often minor (e.g., workman's compensation, product and environmental liability, errors and omissions). In such circumstances it is not so much that moral hazard precludes exchange, it is more that the disadvantaged side must be paid sufficiently. The greater is the moral hazard – the control a cedent has of its losses – the greater the cedent payment must be.¹⁶

The first point to make about moral hazard is that cat-event risks provide relatively limited scope for it. Cat event risks are highly exogenous. So it is not surprising that they have been among the easiest insurance risks to trade. But, in spite of the exogenous nature of cat events, cedents may nevertheless exert some degree of control over their losses. For example, the benefits of aggressive mitigation measures and loss-cost and payment monitoring may not inure to the cedent once cat risk has been transferred. As a result, the cedent may undertake less, increasing potential losses. Superior cat bond structures are those that reduce opportunities for cedent control.

¹⁶The implications of moral hazard can be clearly seen in the cat-bond transaction arranged for St. Paul Re. The protection was intended to cover several lines of business and types of events. As a result, there was a concern that St. Paul Re would have an incentive to grow those lines of business that were less attractive from investors' point of view. To limit the scope for moral hazard, St. Paul submitted the protection to a complicated set of restrictions – taking up some 80 pages in the offering memorandum. Moral hazard was reduced, but at the cost of considerable complexity and opacity.

Dual triggers are a second way in which the scope for moral hazard is reduced. Many cat-bond triggers are linked to individual insurer losses (referred to as ultimate net loss) as a first trigger, but there is almost always a second trigger as well.¹⁷ One obvious second trigger is that the claimed losses be associated with a cat-event as defined by Property Claims Service (PCS). In other instances, the second trigger adds a severity condition to the simple event trigger. Examples would be that a qualifying event must be a hurricane of class 3 or above, or an earthquake of magnitude 5.5, with an epicenter within a specific area.

A third way to reduce moral hazard is to eliminate the ultimate net loss trigger in a client trigger contract leaving the company's protection triggered off the size of industry losses associated with an event. A given company cannot manipulate industry cat losses as much as it can its own cat losses. So moral hazard with respect to industry losses is reduced.

Industry losses can be thought of as a kind of index to which individual company contracts can be benchmarked. The practical problem is that it is not easy to measure industry losses. Collecting data on losses that are directly related to a cat event is difficult. It requires sophisticated information technology to classify claims (and paid losses) as specifically associated with a cat event. Consolidating information across companies is difficult and slow, as each company collects and maintains information in its own way. As a result, existing indexes do not directly measure total industry-wide cat event losses, even though the concept seems straightforward enough.

In practice, different indexes measure different things. An index published by PCS polls insurers in the aftermath of a cat event, asking for estimates of their losses. This index has several virtues. Surveys can be conducted immediately after an event, making the result timely. The surveys are redone as claims come in, allowing for more accurate measures for a given cat over time.

However, the PCS index has major disadvantages. Because it is based on surveys, not hard data, it is difficult – indeed, impossible – to verify the results. Manipulation by reporting companies is possible, and error is likely. Moral hazard therefore remains a concern with the PCS index. In addition, large companies sustain a large proportion of losses. This means that estimation errors by large companies will remain important in the overall industry result. Finally, and most importantly, the index is computed on a state-by-state basis. States are large areas in comparison with cat event footprints. Because many insurers' exposures are unevenly distributed throughout a state, individual insurer losses may correlate poorly with statewide losses. The index therefore provides less desirable protection for an insurer than would a contract linked directly to its ultimate net loss.¹⁸

A second approach to indexing is taken by the newly developed Guy Carpenter Catastrophe Index. It has several advantages as well. The GCCI is based on actual data from participating insurers. This removes guesswork and eliminates the scope for manipulation. These are advantages from investors' perspective. The GCCI also makes it feasible to calculate disaggregated indexes on a zip-code level. This is an advantage from the insurers' perspective, as it affords insurers better correlation with their own losses; insurers can design a portfolio of zip code indexes to match their portfolio rather than rely on a one-size-fits-all statewide index.

The disadvantages of this index are a direct consequence of its use of hard data. Because the data collection requires time and considerable aggregation, GCCI results are available quarterly

¹⁷ When there is more than one trigger, contracts normally require both conditions are met before the cedent is entitled to obtain a recovery.

¹⁸ Contracts linked to the PCS index are traded on the Chicago Board of Trade.

at prespecified times. More frequent updates are not as yet possible. Also, not all insurers report their data to the GCCI. Thus, the index works off a sampling approach, estimating loss-to-value ratios from participating companies within a zip code. These loss-to-value ratios can be aggregated across companies within any zip code, then grossed up to estimate losses within the zip code. Of course, since the sampling approach is what actually makes the hard-data index computation feasible, it may be better to think of it as an advantage. Indeed, statistical work suggests that the sampling errors are reasonably small, especially in view of the index's geographic disaggregation. Finally, the index currently reports only homeowner losses on atmospheric cat events. Commercial / industrial losses and other events (such as earthquake) are not covered.¹⁹

Some cat bonds have been tied to index outcomes rather than ultimate net losses. For example, Swiss Re set up an SPR to provide it with \$112 million in California earthquake protection. The protection and the bonds issued by the SPR were linked to industry losses – measured by the California PCS index – associated with a single earthquake in California. For more details, see Table 1 below.

As already mentioned, indexes help reduce moral hazard on the part of the insurer. They also help standardize cat-event risks, helping investors avoid analyzing the properties of each individual company cat-event risk. These features should, in principle, make index-linked protection cheaper (for the cedent) than indemnification through an ultimate net loss trigger. Currently, because there have been so few transactions, there is not much evidence that indexes are cheaper. But as investors begin to use indexes as benchmarks, a cost disparity should emerge.

Ingredient #5: The loss trigger should be symmetrically transparent

The last important ingredient concerns asymmetric information. It is clearly difficult to cede a risk to another party when it is known that the cedent has superior information. In that case, the buyer (the assumer) is a sheep and the seller a wolf. Cedents who wish to lower the costs of protection have an interest in credibly providing information and transparency about the risk to be sold. However, investors will be concerned that some cedents will not worry so much about the cost of protection. They worry that those cedents who view the cost as cheap are those who know that their risk is worse than appreciated. The effect becomes worse as the cost of protection is higher. Thus, the greater the information asymmetry, the greater the “adverse selection” of transactions against the investor.

There are several points to be made about adverse selection. First, indexes can help reduce informational asymmetries in much the same way that they reduce moral hazard. Investors may credibly know as much about index losses as any particular company would know. A company with risks that are worse-than-appreciated by investors has no particular incentive to link its protection to an index. The reason is that if the company loses more than the index, the company would suffer, not investors.

The second point about adverse selection is that it depends on an asymmetry in buyer-vs.-seller information, and not the *level* of available information. There are no sheep without wolves. For example, it may be impossible for anyone to know how the courts will handle certain environmental or health liabilities in the future. But as long as cedents know as little about the risks as do investors, protection can be obtained, even if very little is known in an

¹⁹ Contracts linked to the GCCI index are traded on the Bermuda Commodities Exchange. See Kenneth A. Froot and Markus F. Mullarkey, “Mid Ocean Limited – Trading Catastrophe Index Options,” Harvard Business School, case no. 9-298-073, April 1998, and *The Guy Carpenter Catastrophe Index*, January 1998, published by IndexCo (www.IndexCo.com).

absolute sense about the risk. Indeed earthquakes and hurricanes are this way. We know very little about when and where the next big event will occur. Yet because much of the ignorance is common to buyers and sellers, protection for such events can be obtained.

The third point is that adverse selection can be mitigated in several ways. First, a high level of disclosure is helpful. Given a cedent's information, it is on average better to raise buyers' information level. Second, companies can incur more damage by being seen as preying on sheep than by paying the cost of protection. For example, faulty products ruin a company's reputation and can severely reduce its market value. Managers, whose compensation is increasingly tied to stock-price performance, have little incentive to produce faulty products, since writers of product liability insurance do not bear the full cost of damage to a firm's reputation. They would prefer to buy product liability insurance for unforeseen matters, but to do everything possible to mitigate the scope for, and effect, of product imperfections.

Looking to the future

Several of the five ingredients are likely to evolve over time. For example, the importance of having a high retention (Ingredient #1) will likely decline. The cause will be a reduction in institutional barriers to issuing lower-rated cat bonds. There is, after all, nothing that says low-rated cat bonds must pay less than high-rated corporate bonds. Certainly, low-rated cat bonds will offer greater yields and commensurately greater risk. But, as with any cat risk placed into a fund, much of the risk is diversifiable. This is true even within catastrophes: combining the risks of California earthquake, East Coast hurricane and North American freeze together with those from outside the US can reduce pooled risk enormously. Funds whose mandates allow them to buy low-rated bonds – perhaps dedicated entirely to cat – will create a market for securitization at lower retention levels.

This institutional evolution is likely to be important in a number of ways. The costs of issuing cat bonds are in large part a function of the volume of issue. If there is little volume, few investment banking groups specializing in these bonds can be supported, and competition will be low. Few investment managers will specialize in the area, so the general level of investor expertise will be low. This will make funds generally less willing to purchase new risks, and will raise the cost to potential issuers considering the capital markets. For these reasons, the market for cat bonds is subject to increasing returns – it will run smoother and more efficiently if the volume of cat issues is relatively high. And, of course, this is self-reinforcing – if the volume of cat issues is higher and costs are lower, more companies will want to use them.

We are already seeing additional investment pools today that will specialize in taking insurance risk. A first group of these will look like traditional reinsurers – raising equity from investors, forming a company, and using the money to write insurance risks. A second group will do something similar, but specifically from tax havens such as Bermuda. This permits an investment that allows funds to compound tax free, and tax-free compounding is valuable to investors. These firms will pursue investment strategies that are particularly tax-disadvantaged, in order to maximize the value of the tax-free compounding they can offer. Note that because such firms can add value by virtue of tax-free compounding their investments, they do not need to add much – or even any – value in their insurance/reinsurance operation.²⁰ Thus, these firms will be a potent source of competition, helping drive down prices of insurance and reinsurance. This is one way of increasing the amount of low-cost capital willing to provide cat event risk capacity.

²⁰ Under US law, it is the existence of the reinsurance/insurance operations that allows the assets to qualify for tax-advantaged status.

A third group will emerge looking more like mutual funds, where investors' put money into a fund (not a company), so that investors own shares of the fund assets. For open-ended funds, these shares will be priced daily on a marked-to-market basis. The fund assets go toward buying cat bonds and other insurance risk securities. Such fund structures will help to reduce the cost of capital. However, this structure also reduces efficiency somewhat, since each fund investment will be on a fully collateralized basis, and the "leverage" employed by insurers and reinsurers is lost. Still, the fund structure will be very important for providing a potentially large and rapidly expandable pool to discipline prices.

Together these three institutional prototypes will provide easier access to capacity when needed. By historical standards, prices will be low. And, in spite of any uncertainty about the absolute level of issuance, a more basic truth emerges: that because of these developments, the "insurance cycle" is fundamentally and permanently changed. In the past, large events depleted balance sheets and triggered enormous increases in prices. Afterward, the high prices encouraged an increase in the amount of capital willing to write risk, but the increase occurred slowly, over several years. As capacity increased, prices would fall again.

These new sources of insurance risk transfer undercut this cycle by disciplining prices. Capital will rush in quickly if prices rise substantially, and this keeps prices from rising in the first place. Prices may rise after a cat, but not nearly to the extent that we have seen in the past. The days of large cycles and extremely profitable underwriting opportunities are over. Competition for capacity is coming to insurance and reinsurance, just as it has come to every other financial services business over time.

If insurers and reinsurers are to survive in this world, they must reduce their costs of capital. One way to do this is to make their businesses and balance sheets more transparent. Increasingly, investment portfolios of these firms are marked to market. Bad news is reflected immediately. This means that problems cannot as easily be swept under the rug and be allowed to build, unobserved, for a long period of time (e.g., the banking crisis of US savings and loans, Japan's real estate loans, etc.). By extension, marking to market of liabilities will help to shrink surprises, reducing moral hazard and adverse selection. Insurers and reinsurers will increasingly be under competitive pressure to do this. Interim trading of cat-event risks will facilitate – even force – this development.

So cat bonds are in fact going to be a powerful force even if we don't see many dedicated bonds issued. The analogy is the way Saudi oil output affects US pump prices, even though the US buys mostly from Venezuela and Mexico. In fact, as cat and other insurance risks become more transparent and familiar to more investors, there will be little need for dedicated cat-event bonds. Corporations will be able to add cat-event clauses to their standard debt issues and get competitive pricing on the combined credit and cat risks. This kind of development will further reduce the costs of issuing cat-linked notes while increasing the amount of risk transfer.

The basic conclusion here is that the vision of a world that switches wholesale from insurance to cat bonds is a *reductio ad absurdum*. Cat risk will be transferred more efficiently as we go forward. The insurance cycle is, for all intents and purposes, gone. But the transfer will occur in many ways – some obvious, some not so obvious. And the cat bond will be only one of many ways to skin the cat.

Table 3

Cat Bond Contract Specifications

Obligor:	Residential Reinsurance Limited, a Cayman Island reinsurance company, whose sole purpose is to provide reinsurance for USAA		
Amount:	Class A-1:	\$164mm	\$87mm principal variable \$77mm principal protected
	Class A-2:	\$313mm	100% principal variable
Yield:	LIBOR plus: 575 basis points for the Class A-2 notes; 273 basis points for the Class A-1 notes. Interest is paid semiannually.		
Loss Occurrence:	A Category 3, 4, or 5 hurricane		
Reinsurance Agreement:	Residential Reinsurance Limited will enter into an reinsurance agreement with USAA to cover approximately 80% of the \$500mm layer of risk in the excess of the first \$1,000mm of USAA's Ultimate Net Loss		
Ultimate Net Loss:	Ultimate Net Loss = amount calculated in Step 6 (below)		
	Step 1	All losses under existing policies and renewals	
	Step 2	All losses under new policies	
	Step 3	9% of the amount calculated in Step 1	
	Step 4	Add the amount from Step 1 with the lesser of Step 2 & 3	
	Step 5	Multiply Step 4 by 1.02 for boat and marine policies	
Step 6	Multiply Step 5 by 1.02 to represent loss adjustments		
Coverage Type:	Single occurrence ²³		
Coverage Period:	June 16, 1997 to June 14, 1998 (see Exhibit 13)		
Ratings:	Class A-1:	Rated AAAs/Aaa/AAA/AAA by S&P, Moody's, Fitch, and D&P, respectively	
	Class A-2:	Principal variable notes are rated BB/Ba/BB/BB by S&P, Moody's, Fitch, and D&P, respectively	
Covered States:	Alabama, Connecticut, Delaware, District of Columbia, Florida, Georgia, Louisiana, Maine, Maryland, Massachusetts, Mississippi, New Hampshire, New Jersey, New York, North Carolina, Pennsylvania, Rhode Island, South Carolina, Texas, Vermont, and Virginia.		

²³ Unlike traditional reinsurance, the form of reinsurance offered by Residential Re. was limited to *one* occurrence. If there was a hurricane that caused \$1,300mm of damage, the contract covered 80% of \$300mm. If there was another storm that produced USAA losses of more than \$1,000mm, USAA would no longer be covered.

¹ For example, if the industry is estimated to have suffered a loss to value ratio of 1.5%, the index will be published with a value of 150.

² California & Western contracts are annual, all others are quarterly (National contract available in both).

- ³ Contract pays 100% of value (\$5,000) if the ending index value is above the option strike value, and pays \$0 otherwise.
- ⁴ Includes the brokerage fee charged by clearing firms to process Members' trades.
- ⁵ CBOT cat option participants post margin equal to the greater of the normal margin maintained by other CBOT option traders (and based on a 20% volatility) and 20% of their maximum potential losses.
