NBER Working Paper No. 9310
October 2002
JEL No. I2, J0

ABSTRACT

While trends in college enrollment for blacks and whites have been the subject of study for a number of years, little attention has been paid to the variation in college enrollment by socioeconomic status (SES). It is well documented that, controlling for family background, blacks are more likely to enroll in college than whites. This relationship is somewhat deceptive, however. Upon closer examination, we find that blacks are more likely to enroll in college than their white counterparts only among low-SES individuals. Among high SES individuals, this pattern is reversed. We also find that this relationship is strongest in the 1970s and appears to disappear over time; by the 1990s, blacks are no more likely to attend college than whites at any end of the SES distribution. This paper first documents this phenomenon and then attempts to understand what is driving these differences across the distribution of family background characteristics and why the relationship is changing over time. Although they have a significant impact on college enrollment behavior, tuition costs and local labor markets explain very little of racial differences in college entry. We do uncover different responses to tuition and labor markets by individuals from different ends of the SES distribution, an important consideration for policies targeted at improving college enrollment for low-SES individuals.

I. Introduction

The distinct pattern of college enrollment for blacks in the last three decades has been an important topic of study, with recent evidence suggesting family background and tuition costs as explanations. In the process, a number of researchers have documented the rather surprising fact that in the 1970s and early 1980s, controlling for family background characteristics, blacks were more likely to attend college than equivalent whites.¹ While a number of papers have examined differing racial enrollment patterns and uncovered this result, very little work has focused on the result itself. To date, this finding remains largely a puzzle.

Upon closer examination, one uncovers the startling observation that blacks at the low end of the family background spectrum are driving this result. That is, low socio-economic status (SES) blacks are more likely than their white counterparts to attend college. At the same time, this story flips at the high end of the SES spectrum; high status blacks are less likely to attend college than equivalent whites. This relationship is strongest in the 1970s and early 1980s and dissipates over time.

The idea that low-SES blacks are more likely than their white counterparts to attend college runs counter to many preconceptions that *low*-income blacks exhibit the worst labor market performance and educational attainment relative to other groups. Anecdotal evidence often suggests that when blacks exhibit better education, employment, or earnings performance, it is only the already well off that reap the lions share of benefits. Indeed, these views are supported if one looks at other outcomes; Bound and Freeman (1992), among others, document the erosion of relative earnings and

¹See for example Cameron and Heckman (2001), Hauser (1993), Catsiapis (1987), and Rivkin (1995).

employment among blacks in the 1980s, noting that the wages of low-educated workers fell but the wages of low-educated black workers fell by more than the wages of their white counterparts. In college enrollment, however, our findings prove false many prior beliefs about racial differences in post-secondary education. During the 1970s and 1980s, out of all groups of blacks, those blacks at the low end of the SES distribution, regardless of how SES is measured, exhibit the strongest college enrollment behavior relative to their white counterparts.

We then turn to possible explanations for this pattern. What becomes clear is that patterns of college enrollment differ not only across races, but also across individuals with different family background characteristics. We focus primarily on the role of college costs and the idea that not only do blacks and whites face different labor markets, but that individuals from different family backgrounds respond differently to their local conditions. We conclude that individuals do respond to differences in college costs and that increases in college tuition have disproportionately affected blacks at the low end of the SES distribution. However, these differential responses explain little of the total variation in college enrollment rates between blacks and whites. Despite this, these findings provide insight into appropriate policies to increase college attendance among the less advantaged.

This paper unfolds as follows. Section II frames the problem we are addressing. Section III describes our data. Section IV establishes the basic patterns in black-white college-entry behavior, while Section V investigates the determinants of college entry using more rigorous tools. Section VI concludes.

II. Previous Literature on Black-White College Enrollment

Black college enrollment has followed an interesting path since the early 1970s (Figure 1). In the late 1970s, black college enrollment increased dramatically, approaching the enrollment rate of whites. In the early 1980s, however, there was a severe drop off. Since that time, black and white college entrance rates have diverged, with blacks falling farther behind.

Both Kane (1994) and Hauser (1993) study the time-series patterns of college enrollment in the CPS.² They find that parental family background is the most significant factor in explaining both the time-series and cross-sectional differences in the data. They assign a secondary role to college tuition, Federal subsidies to college-attenders (the most well-known of which is the Pell Grant program), and labor market variables. The importance of family background has also been documented in a number of other important studies. Fuller, Manski and Wise (1982) and Cameron and Heckman (1998,2001) are examples of this work. Like Kane (1994) and Hauser (1993), Cameron and Heckman (2001) analyze black-white differences in college entry (the latter two papers also look at Hispanic-white differences).

On the cross-sectional front, Rivkin (1995) documents that, in the High School and Beyond Class of 1982, blacks are more likely to attend college than whites with similar math and verbal test scores. He finds that fewer job opportunities for blacks offer a partial explanation, where local labor market conditions are calculated separately by race and gender.

Our study makes three contributions to this literature. First, we establish not only that blacks and whites exhibit college-entry behavior that is different and statistically distinct but also that looking at

²Kane (1994), has tried to explain this trend by focusing on college costs and family background. He finds that the rising cost of college during the 1980s discouraged black college entry, whereas the gains in parental education encouraged black college entry. The net effect is the decline and recovery observed in the 1980s.

mean predicted differences between whites and blacks--as do Kane (1994), Hauser (1992), Rivkin (1995), and Cameron and Heckman (2001) fails to reveal important differences in college entry behavior between blacks and whites across the socio-economic spectrum. We also examine how this relationship has changed over time. Second, we conclude that the effects of college tuition despite its dramatic real increase throughout the 1980s and early 1990s can account for very little of the black-white gap in college entry. Finally, we find evidence that suggests that individuals from different family background respond differently to local labor markets and tuition; as a result, policies that target less-advantaged youth, both black and white, for college attendance must incorporate these different responses.

III. Data

Because we are focusing on both the cross-section and time-series patterns of black and white college entry for men and women, a large data set that provides consistent measures of college going behavior over time is needed. As a result, our primary data source is the March supplement to the Current Population Survey (CPS) from 1968 through 1998. Because this is a household-based dataset, we are able to match 18 and 19 year olds to their parents as long as they are considered members of the same household. While this may sound restrictive, individuals are considered members of their parent's household as long as they either live in their parents' household or live in group quarters away from the household. Therefore, children who are at school living in group quarters are treated as if

they were members of their parent's households.³ As a result, we are able to match 74% of 18 and 19 year olds to their parent's household and personal characteristics.⁴

Previous work on college entry employs the October supplement to the CPS. We believe that the use of the March supplement is an improvement for two reasons. First, the family intra-relationship variable in the October supplement is virtually non-existent prior to 1984. While one can determine if a household member is a head, spouse, or dependent, it is impossible to ascertain if a dependent is a family member. It is therefore impossible to determine if a member is a *child* of the household head.⁵ Second, the background measures in the October supplement, especially income measures, pale in comparison to the March supplement in both quantity and quality (Hauser 1993).

One disadvantage of the March supplement is the absence of an indicator stating if a person received a high school diploma. While the October supplement contains the variable explicitly, the March supplement only reports a person's highest grade attained. For our purposes, therefore, we treat a person who completed the 12th grade as a high school graduate. Regardless of the differences in the data sets, our results are robust across both the March and October supplements.

³Hauser (1993) and Kane (1994) use CPS data from the October supplement and make similar assumptions in order to match 18 and 19 year olds with parental and household characteristics. Cameron and Heckman (2001) note the limitations of this sample selection.

⁴Other 18 and 19 year olds are household heads or spouses of a household head (11.7%), other family members of a household (6.3%) or non-family members of a household (8.3%). By focusing on 18 and 19 year olds, we are not allowing for the possibility that blacks may attend college later than whites. While we cannot test this directly (because of our inability to get family background characteristics for 25 year olds in the CPS), we do look at overall black-white college enrollment patterns for 25 year olds overall and find that they are similar to those of 18/19 year olds.

⁵In fact, a dependent may very well be a sibling or parent of the household head if age distinctions are not carefully noted. In the March CPS, almost 15% of dependents are not the household head's children, which suggests that assigning them as such in the October CPS could affect results.

In this paper, we are examining the college enrollment decisions of 18 and 19 year olds who have completed high school.⁶ Similar to Kane (1994), an individual is considered as enrolled in college if the highest grade attended, prior to 1993, is 13 or higher. As of 1993, individuals are considered enrolled in college if they indicate that they have completed *some college* or if they indicate that they are currently enrolled in college.⁷

Table 1 presents summary statistics of our sample. Whites are more likely to go to college on average, have higher family income, and have more highly educated mothers. Blacks are more likely to be living in a female-headed household with the mother on welfare. They are also more likely to be living in a central city and in the south.⁸

IV. Black versus White College Enrollment: The Facts

The trend in college enrollment for blacks and whites (Figure 1) is striking. Even more striking is this trend when one controls for family background; examining aggregate trends in college enrollment fails to capture important variation by family background. (Table 2) When we break college enrollment down by this SES and compare blacks to whites, we see that, at low ends of the SES spectrum, blacks are actually more likely to attend college than comparable whites. As we move up the SES spectrum,

⁶We focus on enrollment rates for individuals who completed high school. The CPS does not consistently distinguish high school equivalency completers from traditional high school graduates, so we refer to both groups as *high school completers*. Most high school equivalency degrees granted in the U.S. are GED degrees, which require no classroom training to obtain. See Cameron and Heckman (1993) for more details.

⁷We compare our results using the March supplement to the same analysis using the October supplement; in the October supplement, this break occurs at 1983 instead of 1992.

⁸We do not analyze Hispanic college-entry in this paper due to sample size limitations and the changing

this relationship twists and, at the top, we can see that blacks are less likely to attend college than their white counterparts.

Table 2 breaks our sample into 3 periods and presents the average black and white college enrollment rates for all 18-19 year old high school graduates.⁹ The first three rows are at the heart of much of the previous literature. We then break the sample even further into SES groups and present the average rate of college enrollment across the SES distribution. Individuals were assigned an SES group based on an initial regression using the pooled sample by year relating college enrollment to family background characteristics¹⁰. Individuals were then ranked based on their predicted values from this regression; the sample was divided into those in the bottom 20% of the distribution, the middle 60%, and those in the top 20%. Table 2 shows that, in the earliest 2 periods, low SES blacks were more likely to attend college than low SES whites; among the middle and high SES groups, college enrollment is relatively equal for blacks and whites. However, in the latest period, the relationship flattens out and blacks are less likely to attend college at all points along the SES spectrum. Table 3 shows the relationship between family background and college enrollment broken out for men and women; again, we see that the patterns hold for both men and women. As a result, in the remainder of the paper we analyze men and women together when studying differences between black and white college

composition of U.S. Hispanics.

⁹The data are broken into 3 periods for ease of exposition; results are similar when broken down into shorter periods.

¹⁰The index we use to represent SES is, in fact, a measure of the individual's propensity to attend college. This propensity appears to coincide with what we consider to be measures of family background: individuals with lower family incomes and poorer educated parents are less likely to attend college. The probit based on the college enrollment decision merely provides a set of weights for the creation of an index. While these weights are somewhat arbitrary, the results are relatively insensitive to

enrollment.

Table 4 reveals the same pattern in a regression framework.¹¹ College enrollment is regressed on a number of family characteristics, including mother's education, father's education, welfare status, single parent family indicator, family income (log form), income squared, family size (log form), a sex indicator, center city and rural indicators, and dummies for region of the country. In addition, data is divided into 3 periods (1973-78, 1979-89, 1990-1998), which are included as dummies and interacted with an indicator equal to one if the individual is black. Column 1 presents these results. Consistent with the earlier literature, we see that blacks in the earliest period are more likely to enroll in college once one controls for family background. This effect dissipates over time, until, in the latest period, blacks are less likely to enroll in college, controlling for family background.

The impact of the family background variables on college enrollment is quite consistent with expectations. Better educated parents are associated with a higher probability of the child attending college. Controlling for parents education, family income appears to have a negative impact on college enrollment; this may be due to the idea that a “more successful” (i.e. higher income) less educated parent may suggest to a child that there is no need for education, as is the case with a “less successful” (i.e. lower income) well-educated parent. Finally, consistent with the literature, we find that men are less likely to attend college than women, *ceteris paribus* (See Anderson, 2001.)

Column 2 then presents the results when the black dummy in each period is interacted with dummies indicating low SES, middle SES, or high SES family backgrounds. Importantly, we see that it is blacks

our choice of SES measure.

¹¹ All standard errors are adjusted for clustering at the state level.

from low SES backgrounds who are more likely to attend college than their white counterparts; this effect dissipates as one moves up the SES distribution. It is also interesting to note that this impact is strongest in the earliest period; by the middle period the effect is somewhat reduced and it has disappeared by the last period.

It is not surprising that we find that blacks are more likely to attend college at some points during the last 30 years; this finding is consistent throughout the literature. The interesting feature is that low-SES blacks, and not high-SES blacks, are doing better than equivalent whites and thus driving this result. Again, this finding runs counter to the notion that blacks who achieve gains in education attainment tend to be those from high SES backgrounds. Evidence from the 1970s and 1980s directly contradicts the “cream-skimming” argument that well-off blacks are enjoying the benefits of improved education attainment relative to whites.

IV. Explanations

Data sample selection

One possible explanation is that these relationships are merely an artifact of our data selection criterion; we are selecting only those 18 and 19 year-olds who are still dependents of their parents and who also completed high school. We confirm our overall findings with the use of both the October CPS and the National Longitudinal Survey of Youth (NLSY), which suggests that sample selection is not driving our results. In addition, as we noted previously, we are able to match over 70% of individuals to their parents in our sample.

If we delve deeper, we find other reasons to suggest that sample selection is not the primary

explanation of our findings. We test this hypothesis by comparing individuals who we are able to match to their parents at age 18 and 19 to individuals we are able to match to their parents at age 15 or 16 three years prior. At age 15 or 16, the fraction of children who are not part of their parent's household is much smaller; as a result, we are able to look at the family background characteristics of these younger individuals and compare them to our matched sample three years later. In order to explain the relationships that we observe in the cross-section, it would need to be the case that we are somehow selecting better blacks (or relatively worse whites).

From Appendix Table 1 we can see that individuals in our sample are slightly better than the family background of 15 and 16 year olds three years earlier (this is consistent with the fact that, at age 18 or 19, individuals who have already formed their own household are more likely to come from less advantaged family backgrounds). However, this is relatively consistent for both blacks and whites. In fact, it does not appear that there is much selection of our sample, as the means of the family background variables are relatively similar among the 18/19 year olds and the 15/16 year olds three years earlier.

A second concern is that the pattern we observe may be driven by our decision to focus on high school graduates only. However, restricting our sample to high school graduates does not affect our results; we see the same relationship when we consider college enrollment rates relative to the whole population of 18 and 19 year olds. (See Appendix Table 2.) In addition, when we look at the probability of high school graduation by family background characteristics, we see a similar, although much weaker, relationship, suggesting the using the whole population as a control group would only reinforce our findings.

Mis-Measurement of Family Background

When examining the trends in black college enrollment over time, Kane (1994) noted that one part of the story is the improvement in family background characteristics of blacks over this time period. Indeed, the trend is striking; as Figure 3 shows, there have been remarkable improvements in mothers' education--a particularly good predictor of college enrollment--for blacks over this time period. This trend is especially notable among less than high school and high school educated mothers and less pronounced (relative to whites) among more educated women. In much of our analysis we are explicitly controlling for family background characteristics. While these changes are obviously part of the story in explaining what is happening over time, it cannot explain the patterns we observe in the cross section.

Another concern may be that, in the earlier periods, observable family characteristics do a poor job of characterizing the true family background for blacks but do a better job for whites. This could be due to poor labor market and educational opportunities for blacks in the 1940s and 50s, which would make otherwise able individuals choose not to get more education. As a result, although families may appear, based on observables, to have family backgrounds less conducive to higher educational attainment, unobservable parental "quality" among blacks may actually be higher than observable characteristics suggest. As a result, the pattern we see would merely be an artifact of improper classification of blacks. Over time, observable characteristics may become a better measure of family background for blacks, which is why we would observe the cross-section relationship flattening over time.

One observation that refutes this possibility is that we do not see the same pattern when we

isolate the earliest part of our sample, the late 1960s. If it were really the case that weak measures of family background for blacks caused the cross-sectional relationship we observe in the 1970s and early 80s, then we would expect to see the same relationship in the 1960s. But we don't; in fact, we observe the same relationship in the 1960s as we do in the 1990s.

As another test, we considered the extreme case. If comparing blacks and whites with similar family background characteristics is not a valid comparison, as we have assumed thus far, then what if we compare blacks and whites at the same percentile in their own racial distribution of family background characteristics? This methodology implicitly assumes that blacks and whites have the same underlying distribution of family backgrounds, even though observably blacks look worse. To test this, we run regressions of the probability of college enrollment as a function of observable characteristics *separately* for blacks and whites and then rank individuals in each group based on their predicted values. We then compare individuals at the different percentiles in each group; that is, we compare the probability of college enrollment for individuals in the 20th percentile of the black distribution to those in the 20th percentile of the white distribution. Table 5 presents the results when we do this; it allows us to compare college enrollment probabilities for the bottom 20% of the black distribution to the bottom 20% of the white distribution, the middle part of the two distributions, and then the top 20% of both distributions.¹² We can see that the same relationship appears to hold, although it is somewhat weaker.

Blacks at the lower end of their SES distribution still do relatively better than those at the upper end

¹²Note that in earlier comparisons, the bottom 20% of the SES distribution was not calculated separately for blacks and whites; as a result, we were comparing individuals with similar observable family background characteristics instead of blacks and whites at the same points in their own distribution.

relative to their white equivalents. The results of this “extreme” case regression offer convincing evidence that low-SES blacks are outperforming their white counterparts. In Table 5, by assuming a similar distribution of characteristics across the races, we are now comparing whites to blacks who are observably much worse (because, on average, blacks have worse family background characteristics than whites especially at the low end of the SES spectrum). We still see low-SES blacks performing the relative best.

Different Costs and Benefits of College Enrollment

Another explanation is that individuals are behaving optimally, considering costs and benefits, and the observed patterns of behavior reflect responses to different choice sets. When an individual is deciding whether to enroll in college, he/she considers a number of factors. The first is the cost of going to college, both the direct cost in terms of tuition, as well as the indirect cost in terms of the opportunity cost of not working. He also considers the benefit, generally measured as the financial return to going to college. Because these factors can vary across individuals of different socioeconomic status as well as over time, they may be able to explain the pattern we observe in the data. Either blacks face different costs or benefits of going to college, or, facing the same costs and benefits, they respond differently for some reason. We explore whether we see any evidence of this in the data.

The existing literature has already considered the effect of local labor market conditions on college enrollment (See, for example, Rivkin 1995); however, in doing so, they have been limited by a single cross-sectional analysis or have assumed that blacks and whites face the same labor market and therefore include a single measure for blacks and whites (see, for example, Kane 1995). Theory

suggests that strong labor markets will discourage college attendance, as the opportunity cost is higher. However, in general, the average wage as a measure of the opportunity costs tends to work in the wrong direction, as blacks are more likely to live in cities, which have higher wages. Average local wages and unemployment rates have had little success explaining variation in college enrollment.

As mentioned earlier, there is limited work that has considered the fact that blacks face a different labor market from whites. However, the idea that they face different labor markets is consistent with the evidence presented in Bound and Freeman (1992) showing that, from the mid 1970s through the 1980s, there was a widening in black-white earnings and employment gaps among young men, with the gap in earnings widening particularly among college graduates and in the Midwest and the gap in employment widening most among high school dropouts. Figures 4 and 5 show the distinction between black and white labor market outcomes, specifically unemployment rates and the college premium; this disparity between black and white labor market experiences suggests a need for considering them separately.

Finally, the literature has assumed that individuals from advantaged backgrounds respond similarly to costs and labor market conditions as do individuals from disadvantaged backgrounds. This, however, is an empirical question that we test directly. In particular, earlier evidence has suggested that college costs play an important role in determining college enrollment; however, if college costs have a differential impact based on family background, policies targeted at individuals from disadvantaged backgrounds need to incorporate these differences in order to evaluate the potential impact of the policy.

Table 6 tests these hypotheses by examining the relationship between race-specific local labor

market variables, college tuition, and college enrollment. We first present results when coefficients on these variables are constrained to be the same for all individuals of the same race, as the earlier literature has done, and then allow the impact to vary by family background.

We include a number of labor market measures in our regression. Ideally, we would like to calculate labor market variables that vary by race, state, and year. Unfortunately, the March CPS does not contain sufficient observations to calculate such labor market variables. As a result, we calculate time-, race-, and state-varying labor market variables using the Outgoing Rotation for the years 1979-1998.¹³ Because the Outgoing Rotation begins in 1979, we use the March CPS to calculate time-, race-, and *region-varying*, labor market variables from 1973-1979. The March CPS does not provide consistent state identifiers prior to 1976; we use their more aggregate identifier which breaks the country into 21 state groups.¹⁴

Our first measure of local labor market conditions is the unemployment rate, calculated using individuals 25-40 years of age. We calculate it separately for blacks and whites; if blacks faced higher unemployment rates in the market, possibly due to factors such as discrimination, they may be more likely to go to college than observably equivalent whites.

We also consider the relative return to a college education, measured as the ratio of the average wage for college graduates aged 25-40 to the average wage for high school graduates for the same age

¹³Local labor market variables constructed using the Outgoing Rotation are 3 year moving averages.

¹⁴All state-level data was aggregated to the state-group level by averaging across individuals in the states, thereby giving more weight to larger states. From here on in the paper, when we refer to states we are actually referring to state-groups.

group among full time workers.¹⁵ Again, we calculate a race-specific measure, allowing for different returns for blacks and whites in a particular state.

As a measure of college costs, we utilize resident university tuition data from the State of Washington Higher Education Coordinating Board. These data vary by state and by year for the years in our sample. To calculate the appropriate “state-group” tuition, we use a weighted average of state tuitions within the group, with weights given by the respective state population for the given year.

Table 6 presents the results when we estimate probit models of college enrollment for blacks and whites separately. Only the coefficients on the labor market and tuition variables are shown; however, the regressions all include the family background, regional, and center city/rural variables presented in Table 4.

Columns 1 and 3 present the basic results when one includes tuition and local labor market variables in a college enrollment regression. While whites appear to respond as expected to both labor market and tuition variables, this is not true for blacks; in fact, these variables do little to explain what is happening with black college enrollment.¹⁶ Among whites, Column 1 shows that a higher college premium increases college enrollment, as does a higher unemployment rate and lower tuition (although at a decreasing rate as tuition rises). In columns 2 and 4, we allow for differential impacts of these variables by family background category. In the case of both blacks and whites, tuition appears to have a significant impact on college enrollment among low-SES individuals. However, this effect disappears among higher SES blacks, while it holds true among whites of all SES groups. Notably, whites respond

¹⁵A full-time worker is defined as one who worked at least 35 hours the previous week.

¹⁶Note that Kane (1994) finds a significant impact of tuition on college enrollment. This result appears

strongly to labor market variables, with high SES whites responding even more strongly to the college premium than lower SES whites. On the contrary, blacks appear to respond negatively to the college premium. This reflects in large part the fact that blacks appear to respond perversely to the high school wage—as high school wages deteriorated during the late 1970s and early 1980s, it appears that blacks did not respond by enrolling in college, as would be expected. Low SES blacks responded to increasing tuition costs by reducing college attendance, while at the same time low SES blacks did not respond to labor market factors that should encourage college enrollment. To understand the magnitude of their responsiveness, within the relevant range, an increase in tuition of approximately 5% reduces college enrollment of low SES blacks by almost 35%.

These results suggest some important patterns. Among whites, tuition costs and local labor markets appear to have a significant impact on their college enrollment decisions (and these effects are even stronger among high SES individuals). On the contrary, blacks appear to be relatively insensitive (or even responding in a way that is negatively related) to local labor market conditions. Tuition appears to be the only policy variable that has a strong impact on blacks, and only those from poorer family backgrounds.

How much of the variation in enrollment among blacks and whites do these variables explain? Figure 6 presents white college enrollment, black college enrollment, and predicted college enrollment for blacks if they had white characteristics and faced white tuition costs and labor market conditions. (i.e. using black coefficients from table 6 column 4). We can see that, although family background, local labor market characteristics, and tuition costs can explain much of the differences between black and

to be quite sensitive to the model specification.

white college enrollment in the later period, it actually overpredicts black college enrollment in the earlier period.

Although we explain little of the overall variation, the results have important policy implications. Earlier work that suggested that college tuition has an important impact on college enrollment behavior did not consider different responses by individuals from diverse family backgrounds. However, empirical evidence suggests that there may be diverse responses. As a result, efforts targeted at improving college enrollment among disadvantaged individuals must consider the appropriate relationship when evaluating different policies.

V. Other Possible Explanations

Affirmative Action

Anecdotal evidence suggests that affirmative action may be an explanation for the patterns we observe. Clearly, if we knew nothing beyond the positive coefficient on the black dummy in the college enrollment equation, this would seem like a reasonable explanation. In addition, the time series seems roughly consistent with affirmative action: increasing strength in the late 1970s and then declining in the 1980s.

However, when we examine more closely, we see a number of contradictions. First, if there is affirmative action in hiring and wages/promotion, then we would expect our race-varying labor market measures to reflect this; black workers would have lower unemployment rates or higher wages as a result.

If there were affirmative action in college admission, we would expect this to affect blacks

across the SES spectrum and would thereby observe a level shift up of black enrollment instead of the pattern we observe, with low-SES blacks more likely and high-SES blacks less likely to attend college than equivalent whites. In addition, anecdotal evidence also suggests that colleges most likely to admit based on affirmative action would be those who would attempt to Acream-skin@the best black students; in this case, we would expect the opposite pattern from the cross-section we observe.

Directly testing the effects of affirmative action is difficult, however, because of the difficulty in measuring differences in the “effectiveness” of affirmative action in different states at different times. We can, however, compare the patterns we observe in two year- versus four year-colleges. Because many two year colleges have open enrollment, we would not expect to see the same relationship in two-year as in four-year college enrollment if affirmative action is the underlying cause. When we estimate a multinomial logit where the potential outcomes are no college enrollment, two-year college enrollment, and four-year college enrollment (Table 7), we see similar relationships for both types of college enrollment. In the earliest period, the lowest SES blacks are more likely to attend college than the equivalent whites for both two- and four-year colleges. In the middle period, this relationship persists among four year college enrollees but dissipates among the two-year college students. Finally, in the third period, this relationship has disappeared among all students, and blacks are unambiguously less likely to attend either type of college than equivalent whites. These results suggest that it is not affirmative action among the four-year colleges that is driving the relationship.¹⁷

¹⁷We use the October CPS for this estimation because the March does not distinguish between enrollment in two-year and four-year colleges. It is interesting to note that, over this time period, the percentage of blacks attending two year colleges as a fraction of total blacks attending college is remaining relatively constant, as is this number for whites.

Credit Constraints/Pell Grants

There is also a literature that considers the effect of credit constraints on college enrollment decisions. If blacks face different credit constraints than whites, then one might expect to see different patterns of college enrollment by race. Cameron and Heckman (2001) examine this directly to determine whether differences in college enrollment by race are due to differences in family background or differences in the availability of credit. The authors conclude that it is family background, and not credit constraints, that explain the relationship between family characteristics and school attendance. In contrast, Acemoglu and Pischke (2001) exploit changes in the distribution of family income to examine the effect of parental resources on college education and find evidence of large effects of family income on college enrollment.

In the CPS, we do not observe wealth, so it is difficult to test this directly. Our findings on this topic are mixed, however. Though the cross-section pattern we observe runs counter to traditional belief that poorer blacks are more credit constrained than equivalent whites, the fact that we find that tuition has such a strong impact on low SES blacks (and not blacks from wealthier backgrounds) may provide some support for the credit constraint argument.¹⁸

Pell Grants

¹⁸ Another proposed explanation is differences in school quality by race. However, to observe the relationship we see, it would have to be the case that poorer Blacks, who receive lower quality education, are compensating by increasing the quantity. This runs counter to much of the evidence on the relationship between school quality and quantity, which suggests a positive relationship

Finally, Kane (1994) also considers the roll of financial aid in the form of Pell grants and finds little effect of changes in Pell grants on college enrollment. More specifically, he looks at the establishment of Pell grant awards and compares changes in college enrollment for eligible versus ineligible youths before and after the implementation of the program. He concludes that there is little evidence that those to whom the Pell grant program was targeted enjoyed particularly large increases in enrollment.

It is unlikely that changes in Pell grant generosity are driving the relationships we observe in the data. Given that Pell grants are not race-specific but instead are income specific, we should not expect to see differential effects of Pell grants within SES class; low-income individuals should benefit equally regardless of race. Additionally, we see similar results when we allow year*SES effects, which should pick up any changes in the generosity of Pell Grants for low-SES individuals.

However, it may be the case that there are wealth differences among low-SES blacks and whites that we are unable to pick up in our dataset. Because we observe differential behavior by SES and race, this could be consistent with some sort of financial aid/credit constrain story. Further work needs to address this issue, focusing on the differential impact by family background.¹⁹

V. Conclusion

Although it is well-documented in the literature that, controlling for family background

between the two. (See Light and Strayer, 2000).

¹⁹ Consistent with the findings in this paper, recent work by Linsenmeier, Rosen, and Rouse (2002) finds differential effects of financial aid packages on low-income blacks and whites when they focus on one university.

characteristics, blacks are more likely to attend college than whites, very little work has focused on explaining this phenomenon. The literature instead has primarily focused on understanding the time series patterns of black college enrollment.

This paper attempts to understand what is driving this difference between black and white college enrollment. Interestingly, it is not the blacks at the high end of the family background spectrum who are more likely to attend college than their white counterparts; it is the blacks at the bottom of the SES spectrum who are driving this result. In addition, this relationship appears to flatten over time; by the 1990s, blacks at all parts of the SES spectrum are less likely to attend college than equivalent whites.

We examine possible explanations for this phenomenon and make a number of conclusions. First, contrary to earlier evidence, college tuition appears to explain very little of the observed pattern. Interestingly, we do uncover differential responses by individuals from different family backgrounds. As a result, although we explain little of the overall variation in college enrollment, the results have important policy implications. Earlier work that suggested that college tuition has an important impact on college enrollment behavior did not consider different responses by individuals from diverse family backgrounds. However, the empirical evidence suggests that there may be diverse responses. In particular, low-income blacks appear to be very sensitive to changes in tuition costs, while blacks from middle- or high- SES backgrounds are not. As a result, efforts targeted at improving college enrollment among disadvantaged individuals must consider the appropriate relationship when evaluating different policies.

While this paper has focused on differences between blacks and whites, these findings suggest

the need for more extensive research when considering policies directed at the assimilation of more disadvantaged groups into the education system, and future research will extend this analysis to immigrants. It is not surprising that appropriate education policies vary for by race for different target groups. This research suggests that these policies must also take into account different behavioral responses based on family background characteristics as well.
