The Evolution of High Incomes in Canada, 1920-2000

Emmanuel Saez and Michael R. Veall

NBER Working Paper No. 9607

April 2003

JEL No. H2, N3

ABSTRACT

This paper presents new homogeneous series on top shares of income from 1920 to 2000 in Canada using personal income tax return data. Top income shares display a U-shaped pattern over the century, with a precipitous drop during World War II, followed by a slower decline until 1970. Since the late 1970s, top income shares have been increasing steadily and the very top shares are now as high as in the pre-war era. As in the United States, the recent increase in top income shares is the consequence of a surge in top wages and salaries. As a result, series on the composition of incomes within the top income groups from 1946 to 2000 show a dramatic increase in the share of wages and salaries. The parallel evolution of top income shares in Canada and the United States, associated with much more modest marginal tax rate cuts in Canada, suggests that the upward trend in top shares in Canada since the late 1970s cannot be explained by tax cuts. Further evidence suggests that the upward trend in Canada derives from the United States, perhaps because many Canadians have an emigration option.

1. Introduction

The evolution of inequality during the process of development has attracted enormous attention in the economics literature. Many authors have tried to analyze whether changes in inequality are mostly due to changes in technical progress. The Kuznets curve theory is perhaps the most famous example of such an analysis. Kuznets (1955) proposed that income inequality should follow an inverse-U shape along the development process, first rising with industrialization and then declining, as more and more workers join the high-productivity sectors of the economy. In contrast to this technological explanation of inequality patterns, many studies have analyzed whether macro-economic business cycles, government interventions such as tax policy and redistributive programs, or more generally labor market institutions (such as unions) and regulations can have a sustained impact on inequality or explain the time or cross-country patterns in inequality. Understanding better the forces driving inequality is of critical importance to assess the role of government in regulating or shaping the distribution of income and welfare but requires analyzing long-term series of inequality. This study proposes to cast light on this issue by constructing and analyzing income inequality series for Canada over the 20th century.

In many instances, income tax statistics are the only source on income distribution available on a regular annual basis for extended periods of time before micro-economic surveys on incomes became available in the 1950s or 1960s, and remain the best source to study upper income groups. However, income tax statistics cover only taxpayers and thus for some earlier years only the top of the income distribution can be analyzed using tax return data, for example the share of total income accruing to the top decile or top percentile.

Recent studies have used income tax statistics to construct inequality time series for various countries over the course of the 20th century (Piketty 2001a, b for France, Piketty and Saez, 2003 for the United States, and Atkinson, 2001 for the United Kingdom). All these studies have found dramatic declines in the top income shares in the first part of the century but the pattern has been different in

the last two or three decades: an almost complete recovery in the United States, some recovery in the United Kingdom and no recovery in France. The timing of the downturns and upturns suggests that pure technological explanations cannot account for the facts, although other explanations are still tentative.

An important and controversial question that arises is whether the level of top income shares is mainly driven by changes in the tax system. The Canadian situation might cast interesting new light on these issues because of the proximity and similarity of the Canadian and American economies associated with a substantially divergent tax experience in these countries over the last three decades. Therefore, analyzing the Canadian case may offer a good opportunity to assess whether fiscal developments are the main factor driving the pattern of top income shares.

This study uses Canadian income tax statistics from 1920 (the first year such statistics were produced) to estimate homogeneous series of income shares for various upper income groups within the top decile. As personal income taxes in Canada are based on individual income (and not family income), our series measure inequality among individuals (which may be different from inequality among families). In order to understand the evolution of these top income shares, it is important to analyze changes in the composition of these top incomes. We carry out such an analysis from 1946 (the first year details on composition of incomes by income bracket became available). Finally because the evolution of top incomes over the last 20 years is driven mostly by changes in labor income, we also construct shares of total wages and salaries accruing to top wage earners since 1972, primarily using a large micro-economic data set based on tax returns that is only available for more recent years.

Our estimated top shares series show that, similar to the French, British, and American experiences, top income shares in Canada experienced a dramatic drop during World War II with no recovery during the next three decades. However, in contrast to the U.S. experience, top income shares in Canada were not negatively affected by the downturns of the inter-war period. Over the last 20 years, top income shares in Canada have increased

dramatically, almost as much as in the United States. However, this drastic evolution has remained largely unnoticed because it is concentrated within the top percentile of the Canadian income distribution and thus can only be detected with tax return data covering very high incomes. As in the United States, this dramatic increase is largely due to a surge in top wages and salaries. As a result, the composition of income in the top income groups has also shifted dramatically in Canada since World War II: many more high income individuals derive their principal income from employment instead of as a return to capital.

There is a controversy in the United States regarding the role of reductions in marginal income tax rates in the dramatic surge in top incomes. Many authors have argued (see e.g., Slemrod (1996, 1998) and Gordon and Slemrod (2000)) that the surge in top incomes reported on tax returns may not reflect real changes in inequality but rather changes in the way incomes are reported for tax purposes. The Canadian experience casts doubt on this view because Canada experienced a much more modest reduction in tax rates than the United States and yet experienced a very similar surge in top incomes. We present further evidence suggesting that the surge in top incomes in Canada might have derived from the United States as many Canadians have an option to leave Canada to work in the United States. If this brain drain threat explanation is correct, this would imply that the surge in top incomes in the United States has been real as well because it could not have impacted top incomes in Canada otherwise.¹

To the best of our knowledge, this is the first time that the full set of Canadian income tax statistics has been exploited to construct long-term series on inequality in Canada.² Buse (1982) is a related study, which used Canadian

¹ The question of whether the surge in top U.S. incomes is due to supply side effects following the tax cuts (Feldstein, 1995) or to non-tax related effects (Slemrod and Bakija, 2001, Piketty and Saez, 2003) is still debated and the Canadian evidence could be consistent with either explanation.

² Professor A.B. Atkinson has recently and independently produced preliminary distributional series within the top decile of the Canadian income distribution since World War II using Income Tax Statistics. Atkinson's series focus on inequality within the top decile (such as the share of the top decile income accruing to the top percentile) and not on top income shares relative to the average in the population as we do here.

tax statistics from 1947 to 1978. However, his focus was whether the business cycle and the aggregate labor force participation rate could explain the time variation of inequality measures such as the Gini coefficient and various decile shares. In more recent studies, Baker and Solon (1999) use a 1% sample of employer tax records of payouts to employees and Beach, Finnie and Gray (2003) use a 10% version of the same 20% microdata tax return sample we use below. The evidence in both of these studies suggests higher earnings inequality in the late 1990s as opposed to the early 1980s, particularly for males. They also find that most of this trend is due to an increase in permanent earnings variation as opposed to increased earnings instability. In each case, there is no focus on top shares.

Goldberg and Poduluk (1957) compare census data (only available for wage income) between 1930-31 and 1951 and conclude that income inequality fell during this period. Blackburn and Bloom (1993) summarize a number of other studies that examine both individual and family income inequality in Canada in the post-war period. The view that emerges from their summary, their own research as well as the earlier research of Poduluk (1968) and Vaillancourt (1985) is that during the 1950s, 1960s, 1970s, and 1980s there were alternating increases and decreases in family income inequality with not much overall change. None of these studies examines high incomes or the war/pre-war period because they use survey data.

Heisz, Jackson and Picot (2001) summarize more recent Canadian inequality research, including the well-known contribution by Beach and Slotsve (1996). They find that there is some evidence of growing male and family earnings inequality but also emphasize the findings of Wolfson and Murphy (2000) that with respect to income after tax and transfers, the inequality "gap" between Canada and the United States grew between 1974 and 1997.

Our study is in part about the response to tax changes in Canada. Bird and Smart (2001) note only two previous empirical papers on this topic. Sillamaa and Veall (2001) use four years of the same 1982-2000 microdata set that will be used as part of this study and estimate that the response to the 1988 tax cut (the

single largest cut for high-income individuals) over the 1986 to 1989 period was small at lower incomes but large for high-income individuals. Gagné, Nadeau and Vaillancourt (2000) use provincial level data over 1972-1996 and find a large tax responsiveness for high-income individuals, but only for the 1988-1996 period.

The paper is organized as follows. Section 2 describes our data sources and outlines our estimation methods. In Section 3, we present and analyze the trends in top income shares and the evolution of the composition of these top incomes. To cast further light on the recent period, Section 4 presents series of top wages shares since 1972. Section 5 discusses to what extent income tax changes can explain the patterns we obtain and compares these results with the American experience. Finally, Section 6 offers a brief conclusion. All series and complete technical details about our methodology are gathered in appendices.

2. Data and Methodology

In this section, we describe briefly the data we use and the broad steps of our estimation methodology. Readers interested in the complete details of our methods are referred to the extensive appendices at the end of the paper.

Our estimates are from personal income tax return statistics compiled annually by the Canadian federal taxation authorities since 1920.³ Before World War II, because of high exemptions, only about 2 to 8 percent of individuals had to file tax returns and therefore, by necessity, we must restrict our analysis to the top 5% of the income distribution.⁴ Beginning with World War II we can extend our analysis to the top decile, which we divide into finer fractiles. Following Piketty (2001a, 2001b) and Piketty and Saez (2003), in addition to the top decile (denoted by P90-100), we have constructed series for a number of higher fractiles within the top decile: the top 5% (P95-100), the top 1% (P99-100), the top 0.5% (P99.5-100), the top 0.1% (P99.9-100), and the top 0.01% (P99.99-

³ Personal income taxation started in 1917 in Canada. However, the fiscal administration did not produce distribution statistics for the first three years 1917 to 1919.

100). This also allows us to analyze the five intermediate fractiles within the top decile: P90-95, P95-99, P99-99.5, P99.5-99.9, P99.9-99.99. Each fractile is defined relative to the total number of adult individuals (aged 20 and above) in the Canadian population. This number is computed using population census statistics and should not be confused with the actual number of tax returns filed. Column (1) in Table A reports the number of adult individuals in Canada from 1920 to 2000. The adult population has increased from about 5 million in 1920 to almost 23 million in 2000. In 2000, for example, there were 22.8 million adults and thus the top decile is defined as the top 2.28 million income earners, the top percentile as the top 228,000 income earners, etc. Column (2) in Table A reports the actual number of returns filed.

The income definition we use is a gross income definition before all deductions and including all the income items reported on personal tax returns: salaries and wages, self-employment and small business net income, partnership and fiduciary income, dividends, interest, other investment income, as well as other smaller income items. Realized capital gains are not an annual flow of income (in general, capital gains are realized infrequently in a lumpy way) and form a very volatile component of income with large aggregate variations from year to year depending on stock price variations. Moreover before 1972, capital gains were not taxable and hence not reported on tax returns. Therefore, we focus mainly on series excluding capital gains.⁵ It is important to note that our income definition is computed before personal income taxes and personal payroll taxes but after employers' payroll taxes and corporate income taxes.⁶

⁴ We can provide estimates for the top 5% for all years because it is always the case that more than 5% of singles file a return, as opposed to married for whom the exemption threshold was much higher. (See the appendix for details).

⁵In the appendix, in order to assess the sensitivity of our results to the treatment of capital gains, for the period 1972 to 2000, we compute for each fractile (defined by ranking incomes excluding capital gains) the percentage of additional income reported in the form of realized capital gains. We also recompute our top income shares including realized capital gains in income (both for the ranking and the levels and shares computations). For the period 1972-2000, series with and without capital gains display about the same general pattern.

⁶ Using the tables on average income tax paid for each group, one could easily infer the after-tax income shares from the pre-tax income series we report.

Our principal data consist of tables of the number of tax returns, the amounts reported, and the income composition (since 1946), for a large number of income brackets.⁷ As the top tail of the income distribution is very well approximated by Pareto distributions, we can use simple parametric interpolation methods to estimate the thresholds and average income levels for each of our fractiles. For illustration purposes, Table 1 displays the thresholds, the average income level in each group, along with the number of tax units in each group all for 2000, the latest year available. For comparison purposes, in 2000, one US dollar was approximately 1.5 Canadian dollars.

We then estimate shares of income by dividing the income amounts accruing to each fractile by total personal income computed from the National Accounts.⁸ Our income denominator is taken as equal to 80% of Personal Income not including transfers from the National Accounts.⁹ The total income and average income (per adult) series are reported in Columns (4) and (5) of Table A. These series are reported in real (2000) Canadian dollars. Our CPI deflator used to convert current incomes to real incomes is reported in Column (6).¹⁰ The average income series along with the CPI deflator is plotted in Figure 1. Average real income per adult has increased by a factor of five from 1920 to 2000.¹¹ The Great Depression decreased real income by about one third. World War II was a period of very high growth in income. Average income grew steadily from 1950 to 1976. Since then, average income has increased very little with sharp downturns from 1981 to 1983 and from 1990 to 1993.

⁷ However, since 1981, the top bracket is for annual incomes above \$250,000. Therefore, in 2000, the top bracket covers about 0.5% of the total adult population, and the published tax statistics would not allow the study of very small top income groups. Thanks to the microfiles available since 1982 (see below), we can carry over our study of very top incomes up to 2000.

⁸ This methodology using tax returns to compute the level of top incomes, and using national accounts to compute the total income denominator is standard in historical studies of income inequality. For example, Kuznets (1953) adopted this method in his famous study on American inequality.

⁹ Personal Income is higher than total income from tax returns because it includes non-taxable items such as imputed rent, imputed interest, etc. In the recent years in which virtually all adults with income file tax returns, total income from tax returns has always been very close to 80% of personal income net of transfers.

¹⁰ Columns (7) and (8) report the average net tax (including both federal and provincial income taxes) and the average realized capital gain per adult.

After we have analyzed the top share data, we will also analyze the composition of income, concentrating on the period since 1946 when composition data were first published. Using this published information and a simple linear interpolation method, we decompose the amount of income for each fractile into six components: salaries and wages, professional income, business income, dividends, interest income, and other investment income.

Large microfiles of tax returns (covering 20% of the total population) are available beginning in 1982. These microfiles allow us to produce top wage shares series for the period 1972 to 2000.¹² In this case, fractiles are defined relative to the total number of individuals with positive wages and salaries. Wages and salaries include exercised stock options. Estimating the pattern of top wage shares is critical to understanding the pattern of top income shares over the last two decades in Canada.

There are variations in the presentation of published data from year to year and a number of changes in tax law over the period 1920-2000. Therefore, in order to construct homogeneous series, we make a number of adjustments and corrections. The microfiles available from 1982 to 2000 allow us to do exact computations of all our statistics for that period and are a precious source to check the validity of our adjustments for the other periods.

3. Top Income Shares

3.1. Trends

The basic series of top income shares are presented in Table B1. Figure 2 displays the income share of the top 5% (P95-100) from 1920 to 2000. The top 5% share displays sharp fluctuations up to the end of World War II (between 30 and 40% of total income) and is much more stable afterwards (around 25%).

¹¹ Average income during the same period in the United States has multiplied by a factor of four. Population in the United States has also grown more slowly.

¹² Top wage shares for 1972 to 1981 are estimated using the number of tax returns reporting wages and the amount of wages reported by income brackets (see appendix).

Before World War II, the fluctuations are strikingly counter-cyclical. The top share increases sharply during each downturn episode of the inter-war period: the sharp depression of 1920-1921, the Great Depression from 1930-1933, and the pre-WWII downturn of 1937-1938. The top 5% share tends to decrease during the recoveries from the downturns (1921-1923, 1933-1935, and WWII), although the pattern is less pronounced than for the downturns. The top 5% share declines drastically during the World War II years from almost 40% in 1938 to less than 25% in 1945.¹³ This drastic reduction implies that the average income in the top 5% dropped from 8 times the average income before WWII to just 5 times the average income in 1945. After World War II, the top 5% share declines very slowly (with very small fluctuations) from 25% to 22% by the mid 1980s. However, in the last 20 years, the top share has gone up substantially to about 29% in 2000, but is still substantially below its level just before World War II.

Therefore, the Canadian evidence suggests that the twentieth century decline in inequality took place in a very specific and brief time interval, namely the World War II years. This evidence is very much in line with the French (Piketty, 2001a,b), American (Piketty and Saez, 2003), and British (Atkinson, 2001) findings. Moreover, the pattern of the sharp upturns and downturns in the pre-war period suggests that the business cycle was the main driving factor in these fluctuations. As a result, the traditional Kuznets inverted U-curve theory of inequality does not fit well with the Canadian experience over the century. The smooth increase in the top 5% share over the last 20 years seems to fit better with the skilled-biased technology explanations put forward in the case of the United States (see the survey by Acemoglu, 2002). However, even for this later period, we will present further evidence that tends to contradict the technology explanation.

In order to understand the overall pattern of top income shares, it is useful to decompose the top decile into three groups, P90-95, P95-99, and the top percentile P99-100. The share of income accruing to these three groups is

¹³ As we will see in Section 5, in the United States, the fall in top income shares does not start before 1941, providing further evidence that the fall is closely related to the war.

depicted in Figure 3. Three important facts should be noted. First, the counter-cyclical pattern before World War II appears to be stronger for P95-99 than for the top percentile. Second, the drop during World War II is much more substantial for the top percentile (from 18% in 1939 to 10% in 1945) than for the groups P90-95 and P95-99. Third, the upturn during the last two decades is concentrated in the top percentile (which increased from about 7.5% in the late 1970s to 13.5% in 2000). It is striking to note that the P90-95 share did not increase at all from the late 1970s and even the P95-99 share increased by less than one percentage point during the same period.

Examination of the very top groups (P99.9-100 and P99.99-100) in Figure 4 reinforces these three empirical findings. The higher the group, the sharper is the decline during World War II, and the sharper the recovery since the late 1970s. The very top group shares experience a drop of more than 50% from 1938 to 1945. Moreover, and in contrast to lower groups, the drop continues after World War II until the mid-1970s. As a result, the average individual in the top 0.01% had an income more than 200 times the average income in the adult population in 1920. In 1972, that individual had an income only 40 times higher than average. However, since the late 1970s, the very top groups have almost recovered their pre-World War II levels. The top 0.01% share has been multiplied by almost five from 1972 to 2000. In 2000, average income in the top 0.01% is about 190 times the average income.

The fact that the rise in top shares is concentrated in the very top groups within the top percentile explains why this surge in inequality at the top appears to have gone unnoticed in the literature on inequality in Canada. Tax returns are the only data that allow the analysis of groups within the top percentile. This surge in top incomes concentrated within the top groups, as opposed to gains spread more evenly across skilled workers, casts doubt on the skill-biased technology explanation. We will come back to this issue when we focus our analysis on the pattern of top employment income shares in the last two decades. We can also note that there is a short-term spike in top shares in 1989, and that this spike is bigger for the very top groups. We believe that this is

evidence of a (transitory) response to the marginal tax rate flattening consistent with the findings of Sillamaa and Veall (2001). We will discuss in more detail the important issue of the effects of taxation on reported top incomes in Section 5. Finally, the very top groups do not display the same counter-cyclical behavior as other high income groups. The top 0.01% share actually declined during the 1920-1921 downturn and did not increase during the Great Depression.

The remainder of the paper will be aimed at understanding the three key facts: the counter-cyclical pattern of top shares (except the very top share) in the pre-war period, the sharp fall of top shares during World War II (with the most dramatic decline at the very top) with no recovery after the war, and the surge in top income shares over the last 20 years (characterized by an extreme concentration at the top). In order to make progress in our understanding, we now turn to the analysis of the composition of incomes reported by the top groups.

3.2. The Composition of Top Incomes

Canada started publishing detailed information on the composition of incomes by income brackets in 1946. In the early period 1920 to 1945, only tables showing the distribution of occupations for all tax returns were published. Tax returns were classified according to the main source of income reported, such as employment income (employees), professional income (professionals), capital income (financial), and business income (merchants, manufacturers, etc.). These published tables display the number of tax returns in each occupation, and the total amount of taxes paid by each of these groups. The amount of taxes paid can be used to estimate roughly the average income in each category. Therefore, these tables are useful to cast light on the composition of incomes before World War II. Some of this evidence is summarized in Table C1. Important findings emerge from this table.

First, at least two thirds of tax filers are classified as employees during the inter-war period. During and after the Great Depression, the proportion of

employees goes up to more than 80%. During those years, the proportion of tax filers in the adult population was around 3 to 4%. This suggests that well compensated employees formed a very important fraction of the top income earners. Moreover, we expect the fraction of employees to be larger in the bottom groups (within the top decile) than in the very top groups. This is the pattern that arose in the analysis of France (Piketty 2001a,b) and the United States (Piketty and Saez, 2003) and will be confirmed in our analysis on income composition after World War II. This can also be seen in Table C1: when the fraction of tax filers increases in 1930-1932 and 1939-1941 (due to a decrease in exemption levels), the fraction of employees goes up significantly. Therefore, it seems likely that group P95-99 is primarily composed of highly compensated employees during the pre-war period. This explains why the P95-99 share is so clearly counter-cyclical. The sharp downturns of the pre-war period were associated with sharp deflations (see Figure 1). Assuming wages are in general nominally rigid in the short-run, those who are able to keep their jobs during the recession experience a relative gain.¹⁴ This might explain why the P95-99 share increases so much during the downturns (and goes down during the recoveries). As we move up the income distribution, wage earners are replaced by businessmen and rentiers whose incomes are much more pro-cyclical. This explains why the very top shares within the top 1% do not display the same counter-cyclical pattern as the P95-99 share.

Second, the occupation tables also suggest that the very top of the income distribution in the pre-war period was formed of rentiers, as in the United States and France. In order to avoid personal income tax evasion through the accumulation of wealth within corporations (which were taxed at a flat rate substantially lower than the top personal income tax rate) and to provide some relief from double taxation, Canada issued a ruling creating Personal Corporations (see McGregor, 1960) in 1925. Personal Corporations are defined as corporations controlled by a single individual or family and deriving at least a quarter of their profits from passive investments. Therefore personal corporations

¹⁴ We provide further evidence on this point in the following section.

are clearly entities created by passive investors and not owners-managers of businesses. Starting in tax year 1925, Personal Corporations were taxed directly at the personal level (as S-corporations in the United States today). The occupation tables show that taxpayers classified as personal corporations had very large tax liabilities and hence very large incomes, and thus formed a substantial part of the top 0.01% group. Self-employed professionals and entrepreneurs form an intermediate category between the highly compensated employees and the rentiers with personal corporations. Beginning in the tax year 1942, occupation tables were published by income brackets. Table C2 reports the composition of occupations (employees, entrepreneurs, and rentiers) for each fractile. It shows that the fraction of employees is indeed very high for groups below the top percentile and that rentiers formed the majority at the very top. However, the important fact to note is that the fraction of employees remains high, even within the very top fractiles, explaining why even the top shares did not follow the downturns of the pre-war period. This is in contrast with the American and French experiences where the fraction of employees was very small at the top. In those two countries, the share of capital income was much more important at the very top and thus the very top income share dropped during the pre-war downturns.

Our Canadian top share series display a sharp drop during World War II, and that drop is larger for the very top groups. This fall can be in part explained by the fiscal shock in the corporate sector. As part of financing the war, Canada increased substantially taxes on corporations.¹⁵ Moreover, corporations reduced drastically their payout ratios during the war because of the high demand for investment, and perhaps also to avoid the personal income tax which imposed extremely high marginal tax rates (in excess of 90%) on the highest incomes. This is illustrated in Figure 5. Panel A displays the real aggregate value of profits before and after taxes, along with dividend distributions of Canadian corporations

¹⁵ While during the war the corporation income tax itself increased modestly from 15% to 18%, an additional tax was introduced of the greater of 22% of total profits and 100% (part refundable after the war) of profit increases.

from the National Accounts for the period 1926 to 1955.¹⁶ The figure shows that, in spite of a two-fold increase in profits from 1938 to 1945, real dividend payments actually decreased. This explains why top income rentiers experienced a drop relative to the fast growing average adult income (see Figure 1) during the World War II episode. Panel B in Figure 5 displays the share of total capital income (excluding capital gains), and the share of dividends from Canadian corporations in total personal income in the Canadian economy from 1926 to 2000. Consistent with the evidence in Panel A, the share of domestic dividends in personal income falls by more than 60% from 1938 to 1945. Moreover, the share of total capital income (including interest income and distributions from Canadian-owned foreign stock) falls from over 12% in 1938 to about 6-7% at the end of the war. Therefore, these figures show clearly that capital income accruing to individuals was drastically reduced during the War and this might explain why top incomes (composed in large part of capital income) fell so much in relative terms. The other interesting evidence from Figure 5 is that real dividends fell by only a small amount during the Great Depression, even though corporate profits fell to almost zero in 1932 (Panel A). In other words, in the aggregate, firms smoothed their dividend payments and the shock of the Great Depression was almost entirely absorbed by reduced retained earnings. As a result, the share of domestic dividends or more generally capital income in personal income actually grew during the Great Depression (Panel B). This feature is in sharp contrast with the US experience where the share of dividends in personal income fell during the Great Depression and might explain why top income shares (within the top 1%) fell in the United States during the Great Depression while they either increased or remained stable in Canada.

However, the shares of lower income groups (such as P90-95 and P95-99) also fell during World War II, and the evidence from 1942 (and from 1946 on, see below) from Table C2 shows that these groups are composed largely of employees. Therefore, salaries of highly compensated employees must have fallen relative to average earnings in the economy. Unfortunately, there are no

¹⁶ National Accounts series in Canada start in 1926.

data on wage earnings distributions during World War II that we could use to document this on an annual basis.¹⁷ Piketty and Saez (2003), using tabulations of tax returns by size of wage and salaries, were able to show that top wage shares fell significantly exactly during the years of the war. It is very likely that the same phenomenon was taking place in Canada as well, and led to a drop of the bottom groups' shares within the top decile. We present indirect evidence on this issue in Section 4.

From 1946 on, detailed tables on the composition of income were published annually. Therefore, for each fractile within the top decile, we were able to construct series on the composition of incomes. These series are presented in Table C3. Figure 6 shows the composition of income for each fractile in 1946 (Panel A) and 2000 (Panel B). As expected, Panel A shows the share of wage income is a declining function of income and that the share of capital income (dividends, interest, and other investment income) is an increasing function of income. The share of entrepreneurial income (professional and business income) presents an inverted U-shape, and peaks for fractile P99.5-99.9. Thus, individuals in fractiles P90-95 and P95-99 rely mostly on labor income (capital income is less than 25 percent for these groups) while individuals in the top percentile derive most of their income in the form of passive capital income (mostly dividend and estate income). However, it is important to note, as was found in the occupation tables for 1942, that even within the very top groups, wage and salary income remains important. In France and the United States at that time, the share of wages and salaries was much lower at the top than in Canada.

Panel B shows that the income composition pattern has changed significantly from 1946 to 2000. In 2000, the share of wage income has increased for all groups, and this increase is more dramatic at the very top. Entrepreneurial income (professional and business income) has fallen dramatically, especially at the top. The share of capital income (dividends, interest, and other capital

¹⁷ Census earnings distributions are only available on a decennial basis since 1931 in Canada. Earnings for the Prairies provinces are also available for 1936 and 1946.

income, excluding capital gains) has slightly increased below the top 0.5% and fallen significantly for the very top groups. Therefore, both the self-employed or small business owners in the bottom of the top percentile, and the rentiers in the very top, have been in large part replaced by highly compensated employees. Figure 7 shows the evolution from 1946 to 2000 of the share of wage income for various fractiles. The wage share for the groups P90-95 and P95-99 has always been large (around 90% and 75% respectively). However, the wage share within the very top groups has steadily increased over the period. For example, the wage share in the top 0.1% has doubled from 34% to 72% over the period. Interestingly, there has been a reversal in the level of shares between the groups within the top percentile. In 1946, the share of wages was lowest at the top while in 2000, the share of wages (within the top percentile) is higher for the top 0.1% group than for groups P99-99.5 and P99.5-99.9. In 2000, more than two thirds of incomes reported by the top 0.01% individuals is composed of wages and salaries, showing that the working rich have become the main group at the very top and have to a large extent displaced individuals with large capital incomes.

Finally, it should be emphasized that the decline of the share of capital income above the top 0.5% reflects a fall in large capital holdings (relative to the average) rather than a decline in the aggregate capital income in the economy. First, the share of capital income actually increases for the groups P90-95, P95-99, and P99-99.5, showing that top capital income earners have indeed lost relative to the other groups. Second, the series depicted in Panel B of Figure 5 shows clearly that the share of capital income and dividends in personal income from the National Accounts is not lower in 2000 than it was in the pre-war period. We will come back to this in Section 5.

We saw in Section 3.1 that top income shares have increased dramatically over the last 20 years in Canada, and that this increase was concentrated within the top 1%. At the same time, we have shown that the share of wages has also increased dramatically within the top 1% groups. Therefore, there is a strong presumption that the recent upturn in top shares is the consequence of an unprecedented surge in the compensation of the top compensated employees. In

order to cast direct light on this issue, we analyze in the following section the top of the wage income distribution since 1972.

4. The Evolution of Wage Income Inequality

4.1 Wage Inequality in the first part of the century

As we discussed above, Canada did not produce annual statistics on the distribution of wage income in the first part of the century. Therefore, we have to rely on indirect sources to confirm our hypotheses on the evolution of wage income inequality, namely that downturns are favorable to highly compensated employees (relative to the average), and that World War II produced a strong compression in the wage distribution. We use statistics published in The Canada Yearbook and Urquhart and Buckley (1965) showing the number of salary earners (supervisory and office employees with a compensation contract determined at the annual level), and the number of non-salaried employees (workers employed with a compensation contract determined either at the hourly, daily, or weekly level), as well as the total employment income for these two categories of workers. These statistics are based on the manufacturing sector only. Figure 8 displays the ratio of the average compensation of salaried to non-salaried employees (left y-axis), along with the fraction of salaried employees (right y-axis) from 1915 to 1948. It is important to note that the fraction of salaried workers trends upward over time (from 10% in 1915 to 17% in 1948). It seems likely that most of the expansion in the number of salaried workers was low-salary workers, so even in the absence of changes in inequality, we would expect the average salary to fall relative to average non-salary employment earnings. Thus, these series should be used with much caution to analyze long-term trends in inequality. However, two clear facts emerge from the Figure.

First, during the downturns of 1920-21 and the Great Depression, both the fraction of salary earners and the ratio of salary to non-salary employment earnings go up, showing that salaried workers benefited in relative terms from

the downturns. The raw series show that the downturns reduced drastically the number of non-salaried employees while the number of salary earners remained fairly stable. Therefore, this evidence lends credence to our interpretation in Section 3 of the increase of the upper middle income share (P95-99) during the interwar downturns. In contrast to non-salaried employees, well compensated salaried employees were able to retain their jobs during the downturns and experienced only a modest fall in their nominal earnings.

Second, during World War II, Figure 8 shows that both the fraction of salaried employees and the salary to non-salary employment earnings ratio go downward, showing that the relative position of salaried employees clearly declined.¹⁸ The ratio of salary to non-salary earnings decreases from 1.8 in 1939 to a low of 1.3 in 1943 and rebounds only a little to 1.5 in 1946. Therefore, as for our top income share results, the fall is concentrated in the early part of the war (1939 to 1943) and there is only a very partial recovery after the war. The drastic reduction in inequality during the war could be either due to the change in the relative demand for skilled versus unskilled labor to meet the demands of the expanding war economy or to wartime labor regulations and wage controls. The latter explanation is the most direct one and was put forward in The Canada Yearbook, 1948 to explain the trends in salaried versus non-salaried earners observed during the war. The war labor regulations set strict bounds on the raises that corporations were able to give to their “salaried officials” (see Canada, Department of National Revenue, The Wartime Salaries Order, 1945). The higher the salary, the more difficult it was for the firm to provide a raise. For example, raises for employees with salaries above \$7,500 (corresponding roughly to percentile P99.5) required a direct approval of the Minister. These controls, targeted primarily at highly compensated employees, fit well with the evidence showing that the average salary increased very modestly during World War II while average non-salaried earnings rose by more than 50%. The fact that the drop in income shares during the war of the upper middle-class groups

composed mostly of well compensated employees (P90-95 and P95-99) is not followed by a recovery after the war (Figure 3) suggests that the short-term regulations of the war which forced a compression of the wage structure had persistent effects on the distribution of wages many years after the regulations were lifted. This evidence is very similar to the U.S. experience (Piketty and Saez, 2003) and thus gives support to their interpretation that government regulations were very powerful tools to modify the distribution of employment income.

Finally, in light of the U.S. debate on whether inequality dropped during the inter-war period (Williamson and Lindert, 1980, Goldin and Margo, 1992, and Goldin and Katz, 1999), it is interesting to note that both the fraction of salaried workers and the ratio of salary to non-salary earnings are very close in 1922 and 1939. This suggests that, for Canada, wage inequality was stable overall during the inter-war period. Our Canadian series are consistent with the recent occupational ratios (skilled versus unskilled labor) constructed by Goldin and Katz (1999) for the United States over the first part of the century. They show that these ratios fell during both World Wars but were stable during the inter-war period (with a spike during the Great Depression as in Figure 8). This evidence again casts doubt on the technology driven explanations of the pattern of inequality during the process of development (such as the Kuznets inverted U-shaped curve). Our series suggest that external shocks or sharp downturns are the primary events affecting labor income inequality.

4.2 The Recent Surge in Top Wages and Salaries

The microfiles of tax returns, available from 1982, allow a detailed analysis of the wage income distribution where wage income is taken as the employment income of both wage and salary earners. We supplement these with extrapolations based on composition tables published for the years 1972 to 1981

¹⁸ A similar phenomenon takes place during World War I. The ratio of salary to non-salary earnings falls drastically from 2.2 in 1915 to 1.5 in 1918 while the fraction of salary earners goes

to estimate top wage shares by computing the share of total employment income accruing to various upper groups of the wage income distribution since 1972. Our top groups are now defined relative to the total number of individuals with positive wages. Table D1 reports the total number of wage earners, the total wages reported, and the average wage per wage earner for the period 1972 to 2000. Table D2 reports top wage income shares series for the same period. We also report in Tables D1 and D2 the same statistics computed at the family level (instead of the individual level) for the period 1982 to 2000.¹⁹

Figure 9 displays the share of wages accruing to the top decile of the wage distribution. The top 10% wage share has increased steadily over the period from about 25% in the 1970s to 33% in 2000. This increase parallels closely the increase of about 6-7 percentage points in the top 10% of the total income distribution that we analyzed in Section 3.1.²⁰ Figure 10 decomposes the top decile into three groups (P90-95, P95-99, and P99-100). It shows that, exactly as with the total income shares, the increase is concentrated within the top percentile. The shares of P90-95 and P95-99 are almost flat and increase by less than one percentage point while the top 1% share doubles from around 5% in the late 1970s to over 10% in 2000. This probably explains why this dramatic increase in wage inequality has remained unnoticed in the literature on inequality in Canada. Survey data, on which almost all wage inequality studies in Canada have been based, do not allow analysis of the top percentile because of the top coding of reported earnings and because there are very few individuals in the top income groups. Panels A and B of Figure 11 illustrate the extreme concentration of this top wage surge phenomenon. The top 0.1% wage share (Panel A) increased more than four fold from about 1% to 4.3% over the period and the top

up very slightly from 12% to 13.5%.

¹⁹ It is possible to compute those statistics with the microfiles. Families are defined as married couples or single individuals. In that case, the top groups are defined relative to the total number of families (reported in Table D1, col. (2)) with positive wages and salaries. The U.S. wage series of Piketty and Saez (2003) are also defined at the family level.

²⁰ It is interesting to note as well that the level of the top 10% wage share is significantly lower than the level of the top 10% income share. This is due to the fact that non-wage income is more unequally distributed than wage income and that the top 10% income share is computed based on all adult individuals, a significant fraction of which have no incomes (for example non-working spouses), while the top 10% wage share is based on employed individuals only.

0.01% wage share (Panel B) increased even more dramatically from 0.2% to 1.5%. Therefore the top 0.01% of wage earners in 2000 (comprising about 1,400 individuals) earned about 150 times the average wage; the comparable ratio in 1972 was 20. This dramatic change follows closely the evolution of top income shares that we documented in Section 3.1. The spike around the year 1989 is also present in the wage data. Therefore, this evidence shows that the surge in top wages led to a drastic shift in the composition of top incomes away from capital income and toward labor income, as well as to a dramatic increase in top income shares. The series computed at the family level and reported in Panel B of Table D2 display almost exactly the same pattern. Figure A2 in the appendix shows that the increase for the top 1% has been almost identical for individuals and families while the increase for the top 10% has been slightly more pronounced for families. These results show that the increase in the correlation of earnings between spouses is negligible relative to the increase in individual top wage incomes.^{21, 22}

The fact that the rise in top wage shares is so concentrated is a problem for the simple skill-biased technology explanation. It suggests rather that the change in inequality is driven by a change in the compensation practice for highly ranked officers and executives. The comparison with the United States (where the same series have recently been constructed by Piketty and Saez, 2003) is instructive. The United States experienced a similar (both in timing and magnitude) surge in top wage incomes. However, the surge in top wage shares in the United States started earlier (in the early 1970s), was not as concentrated as in Canada and was significant for the upper middle class P95-99 group as well. As a result, in contrast to the Canadian case, studies using survey data such as the Current Population Survey were able to document to a large extent

²¹ The wage series of Piketty and Saez (2003) are estimated for families only (as tax returns are family based in the United States), but in the light of the Canadian findings, it is very likely that the U.S. experienced a surge of similar magnitude in individual top wage shares.

²² The fact that the top decile share increased more at the family level shows that there has been an increase in the correlation of earnings across spouses (especially below the top 1%). Such a phenomenon has been discussed in Canada (e.g., Wolfson and Murphy, 2000) and in the United States (Karoly, 1993).

the surge in high wages (see Katz and Autor, 1999 and Acemoglu, 2002 for recent surveys of these studies in the United States).²³

There seem to be two direct explanations for the similar patterns in the United States and Canada. The first explanation relies on the fact that the two economies have experienced very similar technological change and thus we should expect the distributions of earnings in both countries to follow a similar path. This explanation, however, is not very useful, without defining more precisely what is meant by technology. The second explanation for the parallel pattern at the top might be competition for highly skilled executives driven by the surge in executive compensation in the United States. Top salaries increased enormously over the last three decades in the United States. Moreover, Canadian executives can relatively easily move and find jobs in the United States as part of what is sometimes called the brain drain. Therefore, the only way for Canadian firms to retain their best executives might be to increase their salaries.²⁴

The brain drain threat explanation seems more convincing to us than the technology explanation for a number of reasons. First, European countries experienced the same change in technology as did Canada and the United States. However, a number of these countries, such as France (see Piketty 2001a, b) have not experienced an increase in inequality at the top of the wage distribution.²⁵ Second, if the migration threat explanation is true, then groups with higher mobility costs (or smaller benefits from moving) should experience a smaller rise in their compensation. Three pieces of evidence suggest that this is the case.

²³ Another very important difference between the United States and Canada is the pattern of inequality at the bottom. Low income earners have lost dramatically in the United States relative to Canada, explaining why overall inequality measures such as the Gini coefficient have increased much more in the United States than in Canada (see Blackburn and Bloom, 1993, and Wolfson and Murphy, 2000).

²⁴ Of course, this explanation does not help answering the question of why such a surge in top wages took place in the United States in the first place.

²⁵ British top income shares have increased significantly as well since 1980 although less than in the United States or Canada (see Atkinson, 2001). We expect higher mobility between the United Kingdom and the United States than between continental Europe and the United States.

First, the surge in inequality at the top is more concentrated in Canada than in the United States. The benefits from moving are clearly higher for the very top wage earners (who experienced the greatest increase in compensation in the United States, both in absolute and relative terms). Therefore, a model with fixed costs of moving would suggest that those at the very top in Canada are more likely to move than those in the upper middle class (below the top percentile). As a result, U.S. driven competition should be stronger at the top, producing a more concentrated rise in inequality in Canada than in the United States, as we observed in the data. Finnie (2002) finds that international migration is in fact much more likely among those with high incomes.²⁶

Second, the surge in top income shares started earlier in the United States than in Canada. Figure 12 displays the top 0.5% wage share for the United States (from Piketty and Saez, 2003) and Canada since 1972. The top wage shares were very similar in the United States and Canada in the early 1970s. They started increasing almost 10 years earlier in the United States and are slightly higher in the United States than in Canada today. Iqbal (1999) documents the brain drain and notes that emigration of highly skilled Canadian workers to the United States increased during the 1980s and especially after 1995 when NAFTA (North American Free Trade Agreement) allowed high skilled workers to receive temporary work visa permits much more easily. The brain drain pressures from the United States therefore correspond closely to the increase in top wage shares in Canada, suggesting that the latter might well have been driven by the former.

Third, the French speaking community in Quebec may be more reluctant to move to the United States because of language and perhaps also because of other cultural differences. Finnie (2002) finds that Quebec francophones are much less likely to migrate internationally than residents of other provinces and

²⁶ This is in contrast to the small and mixed income effects he finds for interprovincial migration (Finnie, forthcoming) but consistent with the bivariate comparisons in Graph 7 of Finnie (2001) where he reports that for 1996, 0.89% of Canadians with incomes in excess of \$150,000 migrated internationally, compared to an average for all incomes of 0.12%. See Zhao, Drew and Murray (2000) for similar evidence.

than Quebec anglophones. This is consistent with earlier research (Finnie, forthcoming), which finds a similar pattern in interprovincial migration. As a result, we would expect brain-drain pressures to be weaker for Quebec francophones than for others in Canada. Figure 13 displays the top 1% wage share for francophones in Quebec and for Canadians in all other provinces from 1982 to 2000.²⁷ Figure 13 shows indeed that the rise in the top 1% share has been much more modest for francophones in Quebec (from about 4.5% to 6.5%) than for the rest of the provinces (from less than 6% to more than 11%). Complete series for each group within the top decile (reported in Table D4) display similar patterns.²⁸ Even though top shares start at a higher level in 1982 for Canadians outside Quebec than for francophones in Quebec, the increase in top shares from 1982 to 2000 is larger, even in relative terms, for the former group than for the latter. Interestingly, in contrast to francophones, anglophones in Quebec as a group experience a surge in top wage shares as in the rest of the provinces.²⁹ Therefore, this evidence is consistent with the brain drain threat explanation and would be more difficult to reconcile with the pure technological change explanation as we would expect technological change to spread very quickly from province to province in Canada.

4.3 The Development of Stock Options

The surge in top executive compensation in the United States is due in large part to the development of stock options. In Canada, the development of stock options has been slower because they do not receive a favored tax

²⁷ Francophones are defined as those who complete their income tax returns in French.

²⁸ Very top incomes have also increased significantly for francophones (although much less than for non-Quebec residents). A model where francophones have a higher fixed cost of moving than Anglophones on average would produce such results if the fixed cost (measured in dollars) is independent of income.

²⁹ Actually, the surge in top wage incomes for anglophones is even larger than for the rest of the provinces. The top 1% share increases from less than 7% to over 14%. However, part of this change is due to the fact that the fraction of anglophones within Quebec shrunk from 14.3% in 1982 to 11.5% in 2000. If lower income anglophones left disproportionately, then we would expect the top shares of anglophones to increase mechanically through a compositional effect.

treatment (Klassen and Mawani, 2000).³⁰ In contrast to the United States, profits from stock-option exercises can be separated out from wages and salaries on Canadian income tax returns. In spite of the unfavorable tax treatment, evidence presented in Table D5 and Figure 14 shows the dramatic development of stock options since 1995.³¹ Column (1) in Table D5 shows that, in 1995, stock options represented only 0.26% of total employment income but this number has increased to about 1.5% by 2000. Panel A in Table D5 reports the fraction of the value of stock option exercises in total wages reported by top wage income groups (those fractions for years 1995 and 2000 are also depicted on Panel A of Figure 13). The evidence shows that the fraction of the value of stock-option exercises in total wages reported by top wage groups has also increased dramatically since 1995. For example, the fraction of stock options in wages reported by the top 1% of wage earners increased from 3.3% in 1995 to almost 13.5% in 2000.³² It is also interesting to note the extreme concentration of stock options in the earnings distribution: the top 0.1% wage earners exercise about two thirds of all stock options in each of the years from 1995 to 2000.

It is important to note, however, that stock options, like realized capital gains, are not an annual flow of income. As a result, top income and wage shares produced by ranking taxpayers including stock options might be upward biased as those with stock options have incomes that are unusually high in that particular year. As Canadian tax statistics report separately the value of stock

³⁰In the United States, profits from stock-option exercise are treated like wage income (and hence are deductible from profits for the corporation and taxed like wage income for the individual). In Canada, stock options profits are not deductible for corporations and are in effect taxed very similarly to capital gains for most individuals upon exercise (but are fully reported and included in wages and salaries in the income tax statistics we have used). In effect, 75% of stock-option exercise gains are taxable from 1990 to 1999 (50% before 1988, and 66.6% in 1988 and 1989). Over the course of 2000, the share of taxable stock-option gains was reduced to 50%.

³¹Published statistics in Taxation Statistics on aggregate stock options show that they represented less than 0.1% of total wages up to the year 1992. Hence stock options can clearly not explain the spike of 1987-1989 when top wage shares increased by more than one percentage point. We present evidence only since 1995 because we have to rely on special computations prepared for this study directly by the Canadian Customs and Revenue Agency. Note also that one reason for the increase in the value of stock-option exercises in the late 1990s is the increase in stock market prices at that time.

³² It is therefore very likely that stock options in the United States, which receive a more favorable treatment than in Canada, also represent a large share of wages and salaries reported at the top.

option exercises, we can cast light on this phenomenon.³³ We can first re-compute top wage shares by excluding exercised stock options (both in the numerator and denominator). These top wage shares excluding stock options are reported on panel B of Table D5. However, stock options do represent compensation for labor services and excluding them completely leads to an underestimation of top employment income shares. Therefore, the most satisfactory way to proceed is perhaps to exclude stock options in the ranking of individuals but add back stock options (both in the numerator and denominator) when computing shares. This method eliminates the upward bias due to lumpiness of stock option exercises while taking into account stock options. The top wage shares computed in this way are reported in Panel C of Table D5 and the fraction of stock options for each group (groups defined by ranking of employment income excluding stock options) is reported on Panel D. The salient findings of Table D5 are illustrated in Figure 14. Panel A of Figure 14 shows that the fraction of stock options in employment income is much lower when individuals are ranked by employment income excluding stock options. Even in 2000, the fraction of stock options is only around 10% for the top wage groups when ranked excluding stock options. Interestingly, the share of stock options peaks for group P99.9-99.99 and decreases at the very top. This is in stark contrast with the case where stock options are included in ranking. In the latter case, the share of stock options is steadily increasing as we move up toward the top. This shows that there is substantial re-ranking when stock options are excluded.³⁴ The concentration of stock options, while still substantial, is less extreme when individuals are ranked excluding stock options. The top 1% wage earners (ranked excluding stock options) exercise about two thirds of stock options.

³³ Such an analysis is unfortunately impossible for the United States where stock option exercises are never reported separately in tax or earnings statistics.

³⁴ The dotted graphs on Panel A of Figure 16 show that the same phenomenon was present in 1995 even though stock options were a much smaller fraction of employment income, suggesting that the distributional characteristics of stock options have not changed much from 1995 to 2000, in spite of a dramatic increase in volume.

Panel B of Figure 14 depicts the top 0.1% wage income shares for the three treatments of options we discussed (fully included as in our previous analysis, included in shares but not in ranking, and fully excluded) from 1995 to 2000. As expected, the increase in the top 0.1% wage share is not as dramatic when ranking excludes stock options and even less so when stock options are completely excluded. However, the general pattern shows a steady increase in all three cases. Since 1978, the top 0.1% share would have increased by a factor of 3.5 if stock options were completely excluded instead of by a factor of 4.3 with stock options fully included. When stock options are included only in shares and not in ranking (perhaps the most meaningful economically), this factor is 3.85. Therefore, it is clear that the development of stock options can only explain a small fraction of the rise in top wage shares although it can explain a larger fraction of the surge since 1995. In any case, the re-ranking due to lumpiness in stock option exercises is only a minor element contributing to the surge in Canadian top wage shares over the last 25 years that we documented.³⁵

5. The Role of Taxation and Comparison with the United States

As the empirical literature on behavioral responses to taxation has shown, income taxes can have a substantial impact on incomes reported for tax purposes, on which our top income and wage shares are based. Therefore, it is important to analyze, in parallel to the evolution of top income shares, the evolution of the income tax system. One key measure of the burden of the income tax system is given by the marginal rate of taxation. Such rates, at various percentiles of the income distribution, along with the top marginal tax

³⁵ As discussed in our introduction, Baker and Solon (1999) and Beach, Finnie and Gray (2003) find that most of the recent increase in earnings inequality is due to an increase in permanent earnings variation rather than increased earnings volatility. We leave the question as to whether very high employment income has become more variable for future research.

rate, are reported in Figure 15 from 1920 to 2000.³⁶ A number of interesting findings emerge.

First, up to the early 1970s, the income tax in Canada had a very progressive structure, with many brackets and a very high top marginal income tax rate. However, the top marginal tax rate is a very imperfect measure of the burden of taxation, as extremely few taxpayers had incomes large enough to be in the top bracket. For example, in the early 1920s, the top marginal tax rate was in excess of 70% but the taxpayer at percentile P99.99 (approximately the 500th highest income in Canada at that time) faced a much more modest marginal rate of about 25%. Over the last thirty years, the top marginal tax rate has declined significantly to around 45-50%, but, in the year 2000, a significant fraction of the population - around 5% - faced the top rate.³⁷

Second, the upper middle class below the top percentile (from P90 to P99) has faced a continuously rising marginal tax rate (except the temporary surge of World War II) from negligible rates before World War II, to rates around 20% in the decades following World War II, up to around 35-45% in the last two decades. In comparison, percentile P99.9 faced a rate of about 45% in 1950 and about 48% in 2000. Over that same fifty year period, percentile P99.99 experienced a decline from 55% to 48% and only the super top (around 1,000 individuals within the top 0.01%) had a decline in marginal tax rates of 10 percentage points or more. This stands in contrast with the U.S. case where a much larger fraction of taxpayers (the top 0.1%) experienced reductions in marginal tax rates of more than 30 percentage points from the 1960s and 1970s to the early 1990s.

³⁶ In Canada, provincial income taxes represent a very significant portion of total income taxes. Therefore, Figure 13 displays marginal tax rates including both the federal and provincial income taxes (see appendix for details).

³⁷ This evolution from many brackets extending very far into the distribution of incomes and a high nominal top rate toward a much smaller number of brackets with a lower top rate is a common pattern of most personal income tax systems of developed countries over the 20th century. Income tax systems in the United States, and the United Kingdom, among many others, have also followed the same path. It is an interesting political economy question as to the reasons for this change.

As documented in Piketty and Saez (2003), the United States also experienced a decline in top income shares from the pre-war period to the 1960s and a recent surge in top income shares in the 1980s. Figure 16 depicts the top 0.5% share in both the United States and Canada. The two series are strikingly parallel after World War II.³⁸ The rise in top incomes since the 1980s has been even more dramatic in the United States than in Canada. The rise in top wage shares (within the top percentile) is of about the same magnitude in the two countries since the 1970s (see Figure 12 in Section 4.2).

There is a debate in the United States on the extent to which the rise in top income shares is a tax driven phenomenon. Feenberg and Poterba (1993, 2000) and Feldstein (1995) note that the rise in top incomes has been associated with very large decreases in marginal tax rates for the top groups. However, as pointed out by Slemrod and Bakija (2001) and Piketty and Saez (2003), top income shares in the United States have continued to rise since the mid 1990s in spite of a substantial increase in marginal tax rates in 1993. Also within the United States, various studies have pointed out that the dramatic surge in top incomes in the 1980s might not reflect real income changes but rather changes in the way incomes are reported (see e.g. Slemrod, 1998 and Gordon and Slemrod, 2000). For example, Slemrod (1996) shows that about one third of the jump in the top income shares in the United States from 1986 to 1988 is due to shifts from the corporate sector to the personal sector (as the top personal tax rate became lower than the corporate tax rate after 1987). The Canadian experience casts interesting new light on these issues.

As we saw, high income earners in Canada experienced much smaller reductions in marginal tax rates over the last 20 years. Moreover, as Figure 15 makes clear, during the 1990s an earner at the 90th percentile threshold received a much larger marginal tax rate reduction than those higher in the distribution. Yet

³⁸ In the pre-war era, as explained in Section 3, the top share in the United States declines during the Great Depression while it increases in Canada. This is explained by the larger share of wage income in top shares in Canada and the fact that there was less change in aggregate dividends in Canada than in the United States during the depression. Note also that the drop during World War II starts earlier in Canada than in the United States as Canada enters World War II in 1939, two years before the United States.

as Figures 3 and 4 indicate, the dramatic increase in top income were concentrated in the top percentile.³⁹ As a result, it is less likely that there have been drastic shifts in the way incomes are reported on personal tax returns due to changes in the tax law. Therefore, the dramatic surge in Canadian top reported incomes is more likely to be real and unlikely to be only the consequence of changes in tax reporting behavior.⁴⁰ If, as tentatively argued in the previous section, some of the surge in Canadian top incomes is due to brain drain threats, it must be the case that the surge in top U.S. wage incomes is real and not entirely due to changes in the way incomes are reported for tax purposes. Otherwise, those changes in the United States could not have increased incentives for Canadian top earners to move to the United States. It is important to note, however, that our results are not contradictory with the supply side explanation stating that real changes in top incomes in the United States have been driven by reductions in top marginal income tax rates.

However, even if the long-term increase in top shares in Canada cannot be fully explained by changes in marginal tax rates in Canada, it is interesting to note that in Canada, as well as in the United States, there is clear evidence of short-term response to the cut in marginal tax rates. The most striking example in Canada is the flattening of the tax structure enacted in 1987, which reduced the top rate from 52% (in 1987) to 46% (in 1988) (see Figure 15). The top shares display a sharp increase from 1987 to 1989, which is partially reversed from 1989 to 1990. This spike is much more apparent at the very top than for lower income groups (within the top decile) even though all groups experienced the same decline in marginal tax rates. Actually, the spike occurs only within the top 0.5% of the income distribution. Therefore, as in the United States (see Feldstein, 1995

³⁹ The corporate income tax rate remained relatively stable from the 1950s to 1987, slightly above 50%. The corporate income tax rate was decreased from 1987 to 1990 to about 45%, and has remained stable until 2000. If anything, this small decrease should have induced a shifting out of the personal sector toward the corporate sector.

⁴⁰ In contrast to the United States, the share of business income reported on high income tax returns has been relatively stable and very low, between 1 and 3% of total income over the last 20 years in Canada (see Table C3). This shows that shifts between the corporate and non-corporate sector cannot explain the surge in top incomes in Canada. It is also important to note that, in Canada and in contrast to the United States, there is a dividend tax credit system, which reduced double taxation of dividends over the period.

and Gruber and Saez, 2002), the short-term response to tax changes is much larger for top incomes than for the middle class. The top wage share series display the same spike in 1989 (see Figure 11) suggesting that this short-term response was in large part a wage income phenomenon, with highly compensated employees shifting some of their compensation from the high rate years (1986 to 1987) to the lower tax rate years (1988 and 1989). Such short-term responses of wage incomes have been documented in the United States around the tax rate increase of 1993 (Goolsbee, 2000). Sillamaa and Veall (2001) analyzed the Canadian tax cut of 1988 by comparing incomes in years 1986 and 1989. Consistent with our results, they found significant and large elasticities for high-income groups. However, our top share series show that their elasticity estimates capture the short-term spike response but that this certainly overstates the long-run response to the tax change.

In Sections 3 and 4, we argued that the drop in top income shares during World War II was a combination of a reduction in wage income inequality (probably due to the wage controls during World War II) and a reduction in distributed dividends because of the fiscal shock in the corporate sector during the war. The same phenomenon took place in the United States (see Figure 16). Therefore it is plausible that the same mechanisms were at play in both countries. In 1946, very top Canadian incomes were composed to a large extent of passive capital income (mostly dividends). The absence of recovery after World War II suggests that the rentiers, after the income tax shocks of World War II, were never able to reconstitute fortunes as large (relative to the average income) as in the pre-war period. As argued in Piketty and Saez (2003) in the case of the United States, the most natural and realistic explanation seems to be the creation and the development of the progressive income tax (and of the progressive estate tax and corporate income tax). The wealth that generated the top 0.01% of incomes observed in the inter-war period was accumulated during a time when progressive taxes hardly existed. The fiscal situation faced by wealth-holders during and after World War II in Canada has been substantially less favorable. As shown in Figure 15, groups within the top 0.1% consistently faced

tax rates between 50 and 60% after the war (rates were temporarily much higher during the war). In addition, the corporate tax rate was low before the war (around 10 to 15%) and was consistently around 40-50% after the war. Furthermore, Canada set in place a progressive estate tax with top rates around 50% in 1941 until its elimination in the 1970s.⁴¹

Since the 1970s, the burden of taxation on large capital incomes has been reduced with the repeal of the estate tax and the extension of the dividend tax credit (which reduces substantially the burden of corporate taxation on distributed profits), and the reduction of the top income tax rates. However, it is important to recall that the recent surge in top income shares is mostly a wage income phenomenon and top capital incomes have not yet recovered to their pre-war levels. Nevertheless, the dramatic surge in top wages shares may allow the working rich to accumulate large fortunes, especially given recent reductions in taxes on capital income and estates. As a result, we may very well observe a revival of top capital incomes in Canada within the next few decades.

6. Conclusion

This paper has used personal income tax data to construct homogeneous series of top income shares in Canada over the course of the 20th century. A number of important findings have emerged. First and most striking are the close parallels between the patterns and composition of top incomes in Canada and the United States. Both countries experienced a sharp drop in top shares during World War II with no recovery before the 1970s. However, during the last two decades, the top groups have recovered their pre-war levels. Moreover both countries have experienced the same shift in the composition of top incomes (although this change is less dramatic in Canada than in the United States): until the 1960s, top incomes in both countries were mostly composed of passive capital income and the share of labor income was small. However, the dramatic

⁴¹ The Federal government repealed the estate tax in 1972 and most provinces repealed their estate tax over the course of the 1970s. Quebec was the last province to repeal estate taxation in 1986.

increase in top income shares over the last 20 years is due to a surge in the top wages and salaries. As a result, today the income earners have, to a large extent, replaced rentiers at the top of the income distribution.

The Canadian experience casts interesting light on the role of taxation in explaining the pattern of top income shares. Although the drop in marginal tax rates since the 1970s has been much more modest in Canada than in the United States, the surge in top incomes has been almost as large in Canada as in the United States. The analysis of top Canadian incomes is more transparent because it is not plagued with shifts between the personal and corporate sectors, which have made the U.S. results more difficult to interpret. Moreover, the concentration of the surge in the last decade and among only the very top income shares suggests that fiscal developments in Canada cannot explain the facts. It should be noted, however, that clear evidence of short-term responses to taxation, can be found in Canada as well but that it would be very misleading to equate such responses to the permanent long-run effects of tax changes.

The surge in top wage shares in the last two decades took place in both the United States and Canada but not in other modern economies such as France (Piketty, 2001a,b) or Japan.⁴² Therefore, simple skilled-bias technological explanations cannot account fully for these facts. The surge in top wages in Canada is more concentrated within very top groups than in the United States and was much less pronounced for francophones in Quebec. This suggests that the threat of migration to the United States by highly skilled Canadian executives or professionals may have driven the surge in top wage shares in Canada (while not affecting other countries such as France or Japan). If the migration threat explanation is valid, then this implies that the surge in top reported incomes in the United States since the 1970s must be real to a large extent and cannot be the consequence of changes in the way incomes are reported for tax purposes. The puzzle that still remains to be explained is why such a surge took place in the United States in the first place.

The overall picture that emerges is that no deep technological forces underlying the process of development seem to be driving changes in inequality in Canada, as the famous Kuznets hypothesis suggested. On the contrary, World War II, the development of progressive taxation and changes in top income shares in the United States seem to be able to account for long term trends in Canadian top income shares.

⁴² Preliminary investigation of Japanese tax statistics on employment income suggests that top wage shares have not increased at all over the last two decades and have stayed at a low level (compared to the United States).

APPENDIX

The appendix describes the construction of our top income share series based on tax return data. The Canadian federal income tax started in 1917 and 2000 is the most recent year for which data are available. Starting with the tax year 1920, the Taxation Division of the Department of National Revenue started publishing distributions of taxpayers. These statistics for years 1920 to 1940 were published in the Canada Yearbook and in Incomes Assessed for War Income Tax in Canada (1920-1937) and in Dominion Income Tax Statistics (1938-1939). Many of these statistics, as well as a detailed overview of the income tax legislation for these years, are reproduced in Canadian Fiscal Facts, 1957. After World War II, a much broader set of statistics was published in the annual publication Taxation Statistics covering the years 1941 to 2000. Finally, microfiles of tax returns, based on a 20% random sample of the Canadian population, are available since 1982. This micro dataset of tax returns is known as the Longitudinal Administrative Databank (LAD). The microfiles allow the computation of a much broader set of inequality statistics than the published tables. Aggregate population and National Account statistics are from CANSIM (Canadian Socio-economic Information Matrix) as maintained by Statistics Canada.

A. Total Number of Individuals and Total Income

A.1. Total Number of Individuals

The total number of individuals is computed as the number of individuals in the Canadian population aged 20 and above. These series are based on Census interpolations and provided by CANSIM. CANSIM provides two series for the size of population, one from 1920 to 1971 and a second one from 1971 to 2000. We paste these series using the recent series as the base. The series is reported in Table A, column (1). Upper income groups are defined with respect to this total adult population. For instance, in 2000, with a total adult population equal to 22.81 million, there are 2.281 million individuals in the top decile, 228,100 individuals in the top percentile, etc.

Table A also indicates the total number of tax returns actually filed (col. (2)), as well as the fraction of adult population filing a tax return (col. (3)). Before WWII, due to the high exemption levels, this fraction was low, usually around 5%. The top 5% is therefore the biggest fraction for which we can construct homogeneous estimates for the entire period. We can provide estimates for the top decile only after 1941. Exemptions have been drastically reduced during and after World War II, and therefore the fraction filing have increased dramatically and is around 95% today. Note that the fraction jumps from 80 to 90% in 1978 due a change in the rule for family allowances, which required spouses, even without any income, to file in order to claim the allowances. As a result, in Canada today, almost every adult, even if his or her income is below the exemption thresholds, has an incentive to file an income tax return.

It is important to note that many individuals in the population have no income (before transfers). The biggest group with no income is non-working spouses. The size of this group has shrunk over the century as female labor force participation has steadily increased. This secular phenomenon tends to reduce the size of top income shares over time as income is spread over a larger fraction of the population.

A.2. Total Income Denominator

In order to compute top income shares, we need to estimate total income that would have been reported on tax returns, had everybody been required to file a tax return. We call this total income measure Gross Tax Income (GTI). As only a fraction of the population was filing tax return in the pre-war period, income tax statistics cannot be used to estimate the Gross Tax Income denominator. The natural way to compute such a denominator is to use the personal income series from the National Accounts. Personal income is a broader definition of income accruing to individuals than total Gross Tax Income (had everybody been required to file) for two main reasons. First, personal income includes all transfers from the government (such as welfare benefits, unemployment benefits, or family allowances) and many of these transfers are either partially or not at all reported on tax returns. Therefore, we first subtract transfers (reported separately in National Account series) from the government from the personal income series. Second, various forms of income such as in-kind labor income, imputed rental income of home owners, imputed interest on non-interest bearing bank accounts, etc. are not reported on tax returns but are included in personal income. As a result, it is not surprising that personal income less transfers is systematically higher than Gross Tax Income even in the recent period where practically all income earners file a tax return. Fortunately, the ratio of GTI over Personal Income less transfers has been always around 80% (there are relatively minor fluctuations between 78 and 82% with no trend) since the mid 1970s, when most individuals, even low income earners, started filing tax returns systematically. Before the mid 1970s, because exemptions were larger (in real terms), a number of individuals with small incomes were not required to file tax returns and therefore the ratio of GTI over Personal Income less transfer was smaller (the ratio increased smoothly from 50% in 1945 to around 80% in 1974).

Presumably, a small fraction of individuals with very small incomes do not file tax returns (as total tax returns account for only 96% of the adult population in 2000). On the other hand, a number of individuals below age 20 also file returns. Therefore, we assume that GTI for the total adult population (age 20 and above) had everybody filed a return would be around 80% of Personal Income less transfers. Therefore, our total income denominator is defined uniformly over the period as 80% of Personal Income less transfers from the National Accounts.

The National Accounts provide series of Personal Income and Transfers only since 1926. Therefore, we have extrapolated the series of Personal Income (less transfers) for the period 1920 to 1925 (from Urquhart and Buckley, 1965), assuming that the ratio Personal Income over Gross National Product stays

constant (and equal to 78% as in 1926). This assumption seems reasonable because the ratio Personal Income over GNP stays almost constant over the period 1926-1939. Our total income denominator series (expressed in 2000 dollars) is reported in Column (4) of Table A. The average income per adult is reported in Column (5). The CPI index (base 100 in year 2000) is reported in Column (6).

B. Top Income Shares

Our income definition includes all sources of income reported on tax returns (except government transfers). With the exception of realized capital gains, which became taxable in 1972 (see below), and various government transfers (that are always negligible in the top decile), the definition of incomes reported on tax returns has been very stable since 1920. Since the introduction of the income tax, taxpayers had to report incomes from all sources: wages and salaries for those employed, pensions for retired employees, self-employment income for the self-employed such as doctors or lawyers, profits from sole proprietorship and partnerships for owners of unincorporated businesses such as farmers or retail store owners. Capital income such as interest income, royalties, rents from real estate (as stated above, imputed rent from home ownership was never considered as taxable income), dividend distributions for shareholders of corporations, estate and trust income, and investment income on capital invested abroad were always taxable.

Since 1972, realized capital gains have been partially taxable. From 1972 to 1987, 50% of such gains were included in taxable income. In 1988 and 1989, 66.6% of gains were included in taxable income. From 1990 to 1999, 75% of gains were included in taxable income. Finally, over the course of tax year 2000, the amount of gains taxable has been reduced back to 50%. The later 2000 reform was enacted retroactively and may explain why we do not observe a notable surge in realized capital gains in year 2000.

Most of our series exclude capital gains completely. Tax returns are ranked by income excluding capital gains, and top fractile incomes exclude capital gains. Income shares were computed by using the total income series (Table A, col. (4)), as described in Appendix A. However, to assess the sensitivity of our income series to the exclusion of capital gains, for the period 1972 to 2000, we have also constructed series including full capital gains (i.e., not only the fraction reported on tax returns but the full amount of realized gains). For those series, we rank tax returns by income including full capital gains, and we compute total incomes (including capital gains) accruing to our top income groups. To compute income shares in that case, we add to the denominator described in Appendix A the full capital gains reported on tax returns.

In the text of this paper, we have focused on series excluding capital gains because we cannot include capital gains before 1972. Excluding capital gains also allows getting rid of the very strong short-term volatility induced by lumpiness in capital gains realizations. As a result, to analyze the role of capital gains, it is perhaps more useful to rank income excluding capital gains and see

how much extra income accrues in the form of realized capital gains for each top income group. Therefore, we present three series. The first one (on which we focus in the text) excludes capital gains completely. The second series includes full capital gains both for ranking taxpayers and defining top income groups and in the amounts of income reported. The third series ranks taxpayers by income excluding capital gains (as in the first series) but adds back capital gains in the amount reported (both in the numerator and denominator) to compute top shares. The top fractile incomes series used to compute our top fractile income shares series are reported in real 2000 Canadian dollars in table B3 (for incomes excluding capital gains). For instance, Table B3 indicates that the average top decile income was \$105,262 in 2000, and the top decile income share reported in table B1 for 2000 (42.34%) can be computed by dividing \$105,262 by the average income reported in table A for 2000 ($105,262/24,859=4.234$). The top shares series including capital gains for the period 1972-2000 are reported in Table B2. Panel A reports the series where capital gains are included both in the ranking and the amounts while Panel B reports the series where capital gains are excluded for the ranking but added back to compute the income shares.

The top fractile income series reported in tables B1, B2, and B3 were constructed as follows. For the 1982-2000 period, the series were computed directly from the LAD microfiles. The microfiles allow us to rank tax returns by income excluding capital gains or by income including full capital gains and to compute average incomes without capital gains or with full capital gains for each of our top groups. For the 1920-1981 period, the series were estimated from the published tax statistics tables, according to the following methodology (all computations are available from the authors upon request).

The published tables report the number of returns and tax paid by income brackets. Starting in 1938, the reported income amounts by income brackets are also available. In general, these tables display a large number of income brackets (the thresholds P90, P95, P99, P99.5, P99.9 and P99.99 are usually very close to one of the income bracket thresholds), and one can use standard Pareto interpolation techniques in order to estimate the income thresholds and income levels of the tax unit distribution of income.

B.1. Pareto Interpolation Technique:

The general interpolation technique is based on the well known empirical regularity that the top tail of the income distribution is very closely approximated by a Pareto distribution. A Pareto distribution has a cumulative distribution function of the form $F(y)=1-(k/y)^a$ where k and a are constants, a is the Pareto parameter of the distribution. Such a distribution has the key property that the average income above a given threshold y is always exactly proportional to y . The coefficient of proportionality is equal to $b=a/(a-1)$.

For years before 1938, when the amounts by income brackets are not reported, we first estimate the amounts reported by bracket as follows. We assume that the distribution of income in each income bracket $[s,t]$ is Pareto distributed $F(y)=1-(k/y)^a$. The Pareto parameters a and k are obtained by solving

the two equations: $k=s p^{(1/a)}$ and $k=t q^{(1/a)}$ where p is the fraction of tax returns above s and q the fraction of tax returns above t .⁴³ Note that the Pareto parameters k and a may vary from bracket to bracket. We then estimate the amount reported in bracket $[s,t]$ simply as $Y=N \int_s^t ydF(y)$, where N is the total number of adult individuals in the population (Table A, col. (1)). For the top bracket, this method cannot be applied and we therefore assume that the top bracket is Pareto distributed with Pareto parameters a and k equal to those of the bracket just below the top estimated by the method just described. When data on amounts reported are available (starting in 1938), we verify that our estimated amounts Y are very close to the true reported amounts (in general the true and estimated amounts differ by less than 2-3%).

The first step consists then in estimating the income thresholds corresponding to each of the percentiles P90, P95, P99, ..., P99.99, that define our top income groups. For each percentile p , we look first for the published income bracket $[s,t]$ containing the percentile p . We estimate then the parameters a and k of the Pareto distribution for the income bracket $[s,t]$ as described above. Once the density distribution on $[s,t]$ is estimated, it is straightforward to estimate the income threshold, say y_p , corresponding to percentile p .

The second step consists of estimating the amounts of income reported above income threshold y_p . We estimate the amount reported between income y_p and t (the upper bound of the published bracket $[s,t]$ containing y_p) using the estimated Pareto density with parameters a and k . We then add to that amount the amounts in all the published brackets above t (either directly reported after 1938 or estimated in step one described above).

Once the total amount above y_p is obtained, we obtain directly the mean income above percentile p by dividing the amount by the number of individuals above percentile p . Finally, the share of income accruing to individuals above percentile p is obtained by dividing the total amount above y_p by our income denominator series (Table A, col. (4)). Average incomes and income shares for intermediate fractiles (P90-95, P95-99, etc.) are obtained by subtraction.

B.2. Adjustments to raw Pareto Interpolations:

Published tax statistics tables rank tax returns by net income (1920-1945) or by gross income (1946-2000). Gross tax income is defined as the sum of all sources of income before any deductions. Net income is gross tax income less deductions such as medical costs or charitable contributions allowed but before deducting personal and marital status exemptions. From 1920 to 1928, no deductions were allowed and net income is equal to gross tax income. From 1929 on, charitable deductions were allowed up to 10% of income, and medical expenses (in excess of 5% of income and up to a relatively modest maximum amount) were deductible from income. Starting in 1946, the level of deduction can be computed for each group using the composition tables. In the 1940s and 1950s, this amount fluctuates around 2% for all the income groups within the top

⁴³ This is the standard method of Pareto interpolation used by Kuznets (1953) and Feenberg and Poterba (1993).

decile.⁴⁴ Therefore, we increase our raw income thresholds, levels, and top shares (based on net income) by 2% for all groups in the period 1929-1945.

Starting in 1946, in order to report statistics more quickly, the fiscal administration decided to compile tax statistics about one year after the filing deadline. Because of late filing, a small number of returns were not included in the statistics. To correct for this and based on the Taxation Statistics reports, we increase the number of returns and amounts reported by bracket by 2% from 1946 to 1957 and by 1% from 1958 to 1963. After 1963, the number of missing returns due to late filing is deemed to be extremely small and no correction is made.

For many of the pre-war years, the exemption levels were so high (especially in the period 1925 to 1931) that less than 5% of adult individuals actually filed returns (see Table A, col. (3)). However, the exemption level for singles is always half of the exemption level for married individuals. Thus from 1920 on, it is always the case that more than 5% of single individuals are actually filing returns, although for some years less than 5% of married tax units are filing returns. As a result, the number of taxpayers in the bottom brackets is too low for some years and needs to be adjusted upward. This problem of missing returns is especially acute for years 1925 to 1931. We adjusted for missing married returns using a simple extrapolation method, based on the assumption that marital ratios (i.e. ratios of married individuals to single individuals) across income brackets is constant over those years.⁴⁵

Starting in 1972, a fraction of capital gains is included in gross income and the dividend tax credit is introduced. From 1972 to 1987, 50% of realized gains were included in taxable income. In 1988 and 1989, 66.6% of gains were included in taxable income. From 1990 to 1999, 75% of gains were included in taxable income. Finally, over the course of tax year 2000, the amount of gains taxable has been reduced back to 50%.⁴⁶ The dividend tax credit works as follows. First, dividends reported on tax returns are multiplied by a gross-up factor. This factor was 4/3 for 1972 to 1977, 3/2 from 1978 to 1986, 4/3 in 1987, and 5/4 from 1988 to 2000. Second, a tax credit proportional to the grossed-up

⁴⁴The level of deductions was much lower in Canada than in the United States at the top because the United States allowed unlimited charitable deductions as well as deductions for interest paid on debt.

⁴⁵More precisely, we assume that the ratio of marital ratios over two adjacent brackets is constant from year to year. We verify this assumption comparing these ratios for years with low filing thresholds and where missing returns is not an issue. We use the closest years for which the filing threshold is low enough so that all the married tax units with income in that particular income bracket file a return to compute these marital ratios. We then extrapolate the marital ratio for a year with high filing threshold in a low bracket using the bracket just above for that year and the marital ratios for the year with complete returns. We compute then the expected number of married tax units in each bracket in high filing threshold years. We obtain thus the missing number of returns in each bracket or equivalently a multiplier factor by which we must adjust the actual number of returns to obtain the real number of tax units.

⁴⁶More precisely, 75% of capital gains realized before February 28th, 2000, 66.6% gains realized on or after February 28th and before October 18th, and 50% of the gains realized on or after October 18th, 2000 are included in taxable income. Under the present tax law, for years 2001 and after, 50% of realized gains are included in taxable income.

amount of dividends reported can be deducted from personal income tax liability. This dividend tax credit approximately offsets the corporate income tax paid on profits before distribution to shareholders in the form of dividends.⁴⁷ The important point for our study is that, after 1972, the income tax statistics rank individual taxpayers by gross income, which includes the taxable fraction of realized capital gains, as well as the grossed-up dividend amounts. The series we want to estimate are based on gross income excluding capital gains and including only the actual amount of dividends distributed.

The raw series we compute are based on the income definition reported in the income tax statistics, which include capital gains and grossed-up dividends. Therefore, these raw series are an over-estimate of the income shares based on income excluding capital gains and dividend gross-up. In order to compute our series from the raw series, one could simply deduct for each group the share of capital gains and the grossed-up extra amount of dividends estimated from composition tables. The problem is that ranking according to the income tax statistics and ranking according to our income definition might be different, especially at the very top. For example, in the extreme case where very top incomes of the income tax statistics distributions consist only of capital gains, then the deduction of capital gains would lead to the conclusion that the very top incomes of the income (excluding capital gains) distribution are equal to zero. Therefore, deducting the full amount of capital gains and dividend gross-up would provide an underestimate of the income shares we would like to estimate. However, the LAD microfiles available since 1982 allowed us to compute the magnitude of the corrections that one needs to apply in order to obtain unbiased series from the Taxation Statistics tables for the period 1972 to 1981. More precisely, we computed the correction coefficients to be applied to the thresholds and average income levels for each fractile using the year 1982 for which we have both the imperfect published data and the micro-data, which allows to do exact computations. It turns out that those correction coefficients are pretty stable over the years 1982 to 2000 (the correction coefficients are always in a plus or minus 5% range) and therefore we are confident that the extrapolations we make for years 1972 to 1981 are fairly precise. The top income shares are reported in Table B1 and the income thresholds and income averages for each of our top groups are reported in Table B3.

From 1972 on, we have also computed two alternative series based on income including full realized capital gains.

In the first series, we rank individuals by income including full capital gains and include capital gains in income. After 1982, we use the LAD micro-data to rank individuals by income including capital gains and we compute top income shares in that case by dividing the income amounts for each top group by our total income denominator from Table A, col. (4) plus the total amount of realized

⁴⁷ The offset would be exact if the grossed-up factor and the dividend tax credit rate were equal to the corporate income tax rate. Before 1972, there was no dividend gross-up and the dividend tax credit was 10% of dividends from 1949 (the first year such a credit was introduced) to 1952, and 20% from 1953 to 1971. Since 1972, the dividend credit has fluctuated between 16.66% and 25%.

capital gains corresponding to the amounts reported on tax returns. For the period 1972 to 1981, we have again to deal with the re-ranking issue as only 50% of capital gains are included in gross income and as dividends included are grossed-up. Let us call the sum of the 50% of realized gains excluded from gross income net of the extra dividend gross-up the net missing amount.⁴⁸ Again, simply adding to the amounts estimated from the raw published series the net missing amount would lead to series that are downward biased because of re-ranking. We adopt the same methodology as above to make the corrections for years 1972 to 1981. Namely, we use the year 1982 to compute correction coefficients for each of our fractiles, and we apply those correction coefficients to all years 1972 to 1981. We have also checked carefully that the correction coefficients are stable over the period 1982 to 2000. The top income share series including capital gains are reported in Table B2, Panel A.

In the second series, we rank individuals by income excluding capital gains (as in Table B1), but we add back capital gains in incomes (both in the numerator and the denominator). Exact computations are possible from 1982 on using the LAD micro-data. For the period 1972 to 1981, we adjust our raw series using correction coefficients from the year 1982 (as above). The results are reported in Table B1, Panel B.

B.3. Notes on the pre-war published statistics:

Personal income taxation in Canada has always been assessed on a calendar year basis, meaning that income taxes were based on income earned during a calendar year from January 1st to December 31st. From 1920 to 1940 however, the income tax statistics are reported by fiscal years (ending March 31st) and not by taxation year. Fiscal year means that the amounts and number of individuals were those for which income taxes were collected during the fiscal year April 1st of year t to March 31st of year $t+1$. However, because income tax returns and payments were due in mid-April of the following year, income taxes assessed and collected during fiscal year ending on March 31st of year $t+1$ corresponded almost entirely to incomes earned during calendar year $t-1$ (see Canadian Fiscal Facts, 1957, p. 190). Starting with tax year 1940, the exemptions were lowered significantly in order to increase revenues for the war. As a result the number of returns increased substantially and the fiscal administration was only able to assess 63.7% of all the returns filed for calendar tax year 1940 during fiscal year 1941/42. We assume that the returns assessed were drawn uniformly from all income classes and we simply multiply the number of individuals and amounts reported in the published table by a factor $1/0.637$.

The year 1942 saw the transformation of the income tax from the old system with little or no withholding and where taxpayers paid their tax liability when they filed tax returns in the year following the calendar tax year to a new system of pay-as-you earn where the government implemented widespread withholding as income was earned. In order to relieve taxpayers from having to

⁴⁸ Note that the net missing amount could be negative if the dividend gross-up is larger than the capital gains exclusion.

pay taxes for two years in 1942 (both for year 1941 under the old system and for year 1942 under the new pay-as-you earn system), the tax liability for tax year 1942 was reduced by 50% relative to the nominal tax schedule.⁴⁹

C. Composition of Top Incomes

C1. Occupation Data from 1920-1945

From 1920 to 1945, the fiscal administration published in The Canada Yearbook tables dividing taxpayers in a number of occupational groups. A taxpayer was assigned to a group by major source of income. For example, those who reported wages and salaries as major source of income were classified as employees. We report in Table C1 the fraction of tax returns in each category as well as the fraction of the adult population filing tax returns for each year between 1920 and 1941. After 1941, the number of tax filers increased significantly and thus the figures cannot be compared with the pre-war years.

For tax year 1942, the fiscal administration first published occupation statistics by income brackets (Taxation Statistics, 1947, pp. 108-110). Using the income thresholds from our raw Pareto interpolations, we can estimate the fraction of taxpayers in each occupation for our top income groups. We have grouped occupations into three categories. The Employees category is defined as employees and armed forces. The Entrepreneurs category is defined as Agrarians, Professionals, Salesmen, and Business Proprietors. The Rentiers category is defined as Financial, and Estates. The All Others category is excluded. The results are reported in Table C2.

C2. Composition Data from 1946-2000

We have constructed income composition series for each of our top groups (Tables C3 and C4) for the post World War II period when tables reporting the composition of income, by income brackets, started to be published. The composition series reported in Table C3 indicate for each upper income group the fraction of total income (excluding capital gains) that comes from the various types of income (excluding capital gains). We consider 6 types of income: wage income; professional income; business income; dividends; interest income; and other investment income. Wage income includes wages and salaries, commissions from employment, as well as pensions. Wage income also includes profits from exercised stock options (which are reported as employment income on Canadian tax returns). Professional income includes self-employment income from professions such as doctors, lawyers, etc. Business income includes income from sole proprietorships, partnership income, and farm income. Dividends include only dividends distributed by Canadian corporations (and not dividends distributed by foreign companies to individuals in Canada). Interest

⁴⁹ Higher incomes did not benefit fully from the 50% abatement as tax liabilities above a certain high threshold were to be paid at the time of death of the taxpayer. This deferral rule still made the tax burden for year 1942 much lower than the nominal rates.

includes interest income from banks, mortgages, and annuity income. Other investment income includes rents, fiduciary income, investment income from foreign sources, as well as a number of smaller items. We have excluded from these composition series a number of small income categories such as alimony, taxable social security benefits, taxable unemployment insurance benefits, etc. Taken all together, these small categories never make more 2% of the total income of the top decile (they usually make less than 1%), and even less at the level of the top percentile, and excluding them simplifies the reading of our composition series (these small income categories were taken into account when computing top income levels and top income shares in total income).⁵⁰ For the period after 1982, the composition series were computed directly from the LAD microfiles. For the 1946 to 1981 period, the composition series were estimated from the published tables in Taxation Statistics indicating for each income bracket not only the number of taxpayers and the total amount of their total income but also the separate amounts for each type of income, as well as the deductions, and tax liability. The composition of income within each group was estimated from these tables using a simple linear interpolation method. Such a method is less satisfactory than the Pareto interpolation method used to estimate top income levels (no obvious law seems to fit composition patterns in a stable way), but microfiles show that the resulting estimates are still relatively precise: estimation errors are always less than 2 percentage points, and they are usually much smaller (thanks to the fact that published tables are usually based on a very large number of income brackets).

The composition series reported in Table C4 indicate for each income group the fraction of total income (including capital gains) that takes the form of capital gains for the period 1972-2000. The concept of capital gains used to compute these series is again “full capital gains”, i.e. total pre-exclusion capital gains. We provide two sets of estimates in Table C4 corresponding to the two ways we treated capital gains to compute top income shares (see Panel A and B in Table B2). In the left panel, we report the fraction of capital gains for incomes ranked excluding capital gains (as in Panel B of Table B2). In the right panel, we report the fraction of capital gains for incomes ranked including full capital gains (as in Panel A of Table B2). For the period starting in 1982, these series were computed using the LAD microfiles. For the period 1972 to 1981, a direct linear extrapolation from published tables yields capital gains shares series for groups of income (including the post-exclusion amount of capital gains), and one needs to correct these raw estimates in order to take re-ranking into account (see section above). That is, capital gains shares are smaller for groups ranked by income excluding capital gains than for groups ranked by income including post-exclusion capital gains (as in the published tables), and capital gains shares are smaller for groups ranked by income including post-exclusion capital gains than for groups ranked by income including pre-exclusion capital gains. Microfiles

⁵⁰ The fact that these small income categories almost do not matter for top incomes implies that changes in tax law regarding those items (e.g. changes in the definition of family allowances or unemployment benefits) have negligible consequences for our income levels and shares series.

allowed us to compute the magnitudes of these correction coefficients.⁵¹ The capital gains shares series reported in Table C4 demonstrate that re-ranking is substantial at the very top. For example, in 2000, 26.6% of total income reported by the fractile P99.99-100 of the distribution of income including capital gains takes the form of capital gains, but the capital gains share falls to 6.7% when one looks at the fractile P99.99-100 of the distribution of income excluding capital gains.

D. Wages and Salaries Series

Top wage shares are estimated by Pareto interpolation from the LAD distribution tables from 1982 to 2000 and from Taxation Statistics published tables from 1972 to 1981. The total wage denominator is taken as equal to total employment reported on tax returns. Employment income on tax returns includes wages and salaries, commissions from employment, and other employment income. Wages and salaries include taxable allowances and benefits, bonuses and directors' fee as well as the value of stock-option exercises. Total employment income on tax returns is always very close to 95% of wages and salaries (excluding supplementary labor income) from National Accounts with very little fluctuation over the period 1972-2000. The total number of wage earners is also estimated from LAD (1982 to 2000) and Taxation Statistics (1972 to 1981) as the number of returns with positive wages and salaries. This statistic fluctuates around 100% of the National Accounts estimate of the number of full-time plus part-time employees with no trend over the period (the ratio is always between 98% and 102%). Total employment income and the total number of tax returns with positive wages and salaries amounts are reported from 1972 to 2000 in Table D1.

We estimate two series of top wage income shares. The first series, reported in Panel A of Table D2, are estimated at the individual level (as is our income series). The second series, reported on Panel B, are wage income shares estimated at the family level whereby we add employment income of married couples. In that case, the total number of units (relative to which the upper groups are defined) is the total number of families with positive wage income in the LAD microfiles. The family series are limited to the period 1982 to 2000 when the LAD micro-data are available (as there is no information on earnings by couples in the published statistics). We use the same type of Pareto interpolation methods described in Appendix B to estimate these top wage shares from distribution tables by size of employment income obtained from the LAD microfiles beginning in 1982.

Using the composition Tables published in Taxation Statistics from 1972 to 1981, we are able to extend our individual wage shares series back to 1972. Starting in 1972, the composition tables by brackets of total income report not only the amounts of wages and salaries reported but also the number of tax

⁵¹ The correction formulas for capital gains shares that we inferred from microfiles are more complex than those applied to correct income levels, and they are available upon request.

returns with positive wages and salaries. We use this information to obtain a preliminary distribution of wage income as follows.

Average wage income for wage earners and average gross income for each gross income bracket are computed. We then assume that each gross income bracket corresponds to a wage income bracket with thresholds equal to the actual gross income thresholds multiplied by the ratio of average wage income to average gross income in that bracket. In order to generate brackets fitting together, the final thresholds are taken as equal to the average of the corresponding top and bottom thresholds of two adjacent brackets. We therefore obtain a set of wage bracket thresholds where the number of returns and the wage amount reported for each bracket is the same as in the original composition table. This new distribution by size of wages is not perfectly accurate because ranking in terms of gross income is not identical to ranking in terms of wages. From this constructed wage income distribution, we compute average income levels and shares for each of our top income groups. The levels and shares are underestimated using this method because ranking in terms of total income is not identical to ranking in terms of wages and salaries.

This method is therefore reliable only if wage income is a substantial fraction of income bracket by bracket. This is true below the top percentile but not for the top wage income groups. However, using years 1982 to 2000 where both the microfiles and the published composition tables are available, we can estimate by how much levels and shares estimated from published tables for each top income group should be adjusted to match estimates from the microfiles. Fortunately, these multiplier factors are extremely stable from 1982 to 2000 (the maximum variation between multipliers is always less than 10%). Therefore, we can use the multipliers from year 1982 to adjust the levels and shares for years 1972 to 1981.⁵²

We repeat these computations for all provinces excluding Quebec and for francophones in Quebec separately for years 1982 to 2000.⁵³ Each tax return identifies the Province of residence, and francophones and Anglophones within Quebec are identified according to the language of their tax returns. For these series, the total number of individuals is defined as the number of individuals in the LAD microfiles in that particular group with positive wages and salaries, and the total amount of employment income is defined as total employment income reported on tax returns for that particular group. Canadians are free to choose to file their tax returns in either English or French. Quebec is the only province with a strong majority of francophones. Quebec residents filing tax returns in French are almost certainly francophones. It might be the case, however, that some Quebec francophones may file tax returns in English. However, our conclusions on the differential trends for Quebec francophones and the rest of Canada

⁵² Shares and levels are blown up by around 5% for groups P90-95 and P95-99, by around 10% for groups P99-99.5 and P99.5-99.9, and by around 20% for groups P99.9-99.99 and P99.99-100.

⁵³ Published tables in Taxation Statistics do not allow the estimation of these series for years when the LAD microfiles are not available.

remain valid as long as the share of top earner francophones who file tax returns in French does not decline over time.

Data on stock options exercised for the period 1995-2000 have been provided by the Statistics Division of Canada Customs and Revenue Agency. The Agency provided us with two set of statistics.

First, wage earners were ranked by full employment income including stock options and the number of individuals, the amount of employment income they reported, as well as the amount of stock option they exercised was reported for a range of full employment income brackets. From these statistics, we estimated, using the methods described above, the share of stock options in employment income for each of the top groups. Those statistics are reported in Panel A of Table D5 (note that the share of employment income accruing to each of these groups had already been estimated and reported in Table D2).

Second, wage earners were ranked by employment income excluding stock options and the number of individuals, the amount of employment income they reported, as well as the amount of stock options they exercised was reported for a range of employment income (excluding stock options) brackets. From these statistics, we estimated the shares of employment income (excluding stock options) accruing to each of the top wage groups (ranked by employment income excluding stock options). These statistics are reported on Panel B of Table D5. Keeping the ranking by employment income excluding stock options, we estimated the share of employment income (including stock options) accruing to each of these top groups (ranked by employment income excluding stock options) by adding back the amount of stock options reported both in the numerator for each group and the denominator. Those top wage shares are reported on Panel C of Table D5. Finally, for each of these groups, we estimated the fraction of stock options they reported (computed as the amount of stock options divided by the amount of employment income including stock options). Those statistics are reported on Panel D of Table D5.

E. Estimating Marginal Tax Rates and Average Tax Rates, 1920-2000

The Canadian income tax structure has gone through many reforms over the course of the century. Perry (1955, 1989) provides a comprehensive description of the development and evolution of taxation in Canada during the pre-war and post-war periods respectively.

Marginal tax rates reported in Table E1 have been computed as follows. We consider each of the raw income thresholds P90, P95, etc. estimated from the interpolation methods described in Section B. We then assume that the taxpayer at each of these income thresholds is a married taxpayer (who can claim the married exemption level) with two dependents (for example a married couple with two children under 18). We therefore subtract from raw income the married exemption and two dependent exemptions. We also subtract the average level of deductions claimed on top of marital and personal exemptions at

the corresponding percentiles to obtain net taxable income.⁵⁴ Tax liability is then obtained from taxable income from a standard tax schedule with increasing marginal tax rates by income brackets, from which the marginal tax rate for any taxable income level can be easily obtained. The marginal tax rate we report includes all surtaxes, as well as the provincial tax rate (see below).

For some years, surtaxes apply only to some forms of income such as investment income. Similarly, dividends from Canadian corporations often face a lower marginal tax rate. In those cases, we have assumed that the marginal dollar earned by the taxpayer has the same composition as total income for the average taxpayer in that percentile.⁵⁵ For the period 1949 to 1971, we have taken into account the dividend credit to reduce the marginal tax rate according to the share of dividend income accruing at each percentile. Starting in 1972, in addition to the dividend tax credit, dividends were grossed-up before being included in income. As a result, for high income earners in a high tax bracket, the net marginal tax of received dividends was very close to the marginal tax on ordinary income and therefore we assume that dividends are taxed as normal income when computing our marginal tax rates.

Before 1942, some provinces and municipalities levied personal income taxes. The two biggest provinces, Ontario and Quebec did not introduce provincial income taxes before 1935 and 1941 respectively.⁵⁶ Therefore, we do not try to add these provincial taxes in our computations of marginal tax rates and tax liability in the pre-war period. During World War II, the provinces agreed to stop raising income taxes and let the federal government collect all income taxes. After World War II and up to 1961, all Provinces (except Quebec) worked on a tax rental agreement whereby the federal government would collect all income taxes and redistribute part of income tax collections to each province. Therefore before 1962, the federal income tax liability includes both federal and provincial income taxes. Starting in 1962 and up to 1971, tax collection agreements were passed whereby the federal government granted abatements from federal income taxes and provinces would receive in provincial taxes amounts equal to the abatement from federal income taxes. Therefore for years before 1972, we simply use the federal income tax structure to compute marginal tax rates, as well as tax liabilities reported in Taxation Statistics.

Starting in 1972, the nominal federal tax rate was lowered but each province defined a given percentage that the federal tax administration would collect on behalf of the Province on top of the nominal federal income tax. In Table E1, we have used the case of Ontario (the largest province containing

⁵⁴ For years 1920 to 1928, no additional deductions were allowed. For 1929 to 1945, we have assumed that deductions amounted to 2% of gross income at all percentiles (which is true on average for year 1946, the first year these details are available). From 1946 to 2000, the level of deductions increases slightly over time and we have made approximate computations for each year and percentile threshold using the available tables from Taxation Statistics.

⁵⁵ For example, if the taxpayer in percentile P99.9 reports on average 30% investment income, and 70% labor income, and the marginal tax rate for investment and labor income are t_1 and t_2 respectively, we estimate the marginal tax rate as $t = 0.3*t_1 + 0.7*t_2$.

⁵⁶ Some large cities in these provinces had, however, established modest income taxes since the beginning of the century or even before.

more than half of the highest incomes in Canada) to compute marginal tax rates. Over the years, the Ontario provincial tax has changed many times and special provincial surtaxes have been introduced as well that have in part offset the decline in progressivity of the federal tax system. All these surtaxes have been included in the estimation of marginal tax rates reported in Table E1. Marginal tax rates for other provinces have followed a very similar time pattern as rates for Ontario. Quebec in particular has almost always had marginal rates slightly higher than Ontario (by 2 to 4 percentage points in general).

Average tax rates have been computed as the sum of federal and provincial tax liability (after surtaxes and net of all credits) paid by each group divided by total gross income (including only the taxable portion of capital gains for the 1972 to 2000 period) reported by each group. We have decided to include the taxable portions of capital gains in the income denominator so that our average tax rate measures reflect the average tax on ordinary income. For years 1982 to 2000, we have used the LAD microfiles to do these computations. In the period 1920 to 1981, we have used the distribution tables, which always report the amount of taxes paid by income brackets.

Table 1
Thresholds and Average Incomes in Top Groups within the Top Decile in 2000

Thresholds (1)	Income level (2)	Fractiles (3)	Number of tax units (4)	Average Income (5)
		Full Population	22,807,585	\$24,859
P90	\$59,232	P90-95	1,140,379	\$66,310
P95	\$75,670	P95-99	912,303	\$95,982
P99	\$145,774	P99-99.5	114,038	\$171,728
P99.5	\$210,150	P99.5-99.9	91,230	\$303,035
P99.9	\$530,311	P99.9-99.99	20,527	\$923,385
P99.99	\$2,396,050	P99.99-100	2,281	\$4,695,923

Notes: Computations based on income tax return statistics (see Appendix Section A).

Income defined as annual gross income excluding capital gains and before individual taxes.

Amounts are expressed in 2000 Canadian dollars. 1 US dollar = 1.5 Canadian dollar.

Notes: Population estimates based on census data, from CANSIM. Total income is 80% of personal income (less transfers) from National Accounts. Consumer Price Index (CPI) from CANSIM series. Average tax per capita includes both federal (and provincial) individual income taxes. Average capital gains per adult based on total capital gains (taxable and non-taxable) reported on tax returns since 1972. All details in Appendix Section A.

Notes: Computations by authors based on tax return statistics. See Appendix Section B for details.
Series for P90-95 are estimated only for the 1941-2000 period because the tax return population does not cover that group in the pre-war period.

Table B2: Top Income Shares Including Capital Gains in Canada, 1972-2000

Notes: In Panel A, tax returns are ranked by total income including full capital gains, and shares are computed as total income and capital gains accruing to upper groups divided by total income plus total capital gains in the economy (from Table A). In Panel B, individuals are ranked by income excluding capital gains (as in Table B1) but capital gains are added back (in both the numerator and the denominator) to compute top shares. All details in Appendix Section B.

1935	3.25%	80.69%	0.43%	3.24%	3.83%	0.28%	6.42%	0.25%	4.86%
1936	3.49%	80.03%	0.42%	3.25%	4.13%	0.29%	6.31%	0.24%	5.33%
1937	3.84%	81.33%	0.49%	2.95%	3.81%	0.30%	5.97%	0.25%	4.90%
1938	4.19%	77.54%	0.59%	4.04%	5.35%	0.58%	6.21%	0.31%	5.38%
1939	4.22%	77.44%	0.62%	3.68%	5.59%	0.56%	5.09%	0.26%	6.76%
1940	8.42%	87.44%	0.38%	2.00%	3.33%	0.26%	3.22%	0.13%	3.24%
1941	11.86%	86.60%	0.85%	1.82%	5.11%	0.28%	3.07%	0.11%	2.16%

Notes: Computations based directly on published tax return statistics (see Appendix Section C for details)

Percentiles are based on average tax paid for each category.

Table C2: Shares of each Occupation within the Top 10% in 1942

Fractile	Number of	Employees	Entrepreneurs	Rentiers
(1)	Individuals	(3)	(4)	(5)
P90-95	361,443	91.8%	6.9%	1.3%
P95-99	289,154	83.2%	14.1%	2.8%
P99-99.5	36,144	59.4%	33.5%	7.1%
P99.5-99.9	28,915	52.0%	36.5%	11.5%
P99.9-99.99	6,506	46.7%	30.0%	23.3%
P99.99-99.999	651	38.3%	18.1%	43.6%
P99.999-100	72	27.3%	8.1%	64.6%

Notes: Computations based on interpolations from Taxation Statistics, 1947, pp. 108-110. See Appendix Section C.

Category Employees defined as employees and armed forces. Category Entrepreneurs defined as Agrarians, Professionals, Salesmen, and Business Proprietors. Category Rentiers defined as Financial, and Estates. Category All Others excluded. Tax returns are classified in occupation categories by main source of income.

Table C3: Income Composition by Sources of Income and by Fractiles of Total Income (excluding capital gains) in Canada, 1920-2000

Notes: In Panel A, tax returns are ranked by total income excluding capital gains. Series report the additional income reported in the form of capital gains. The share of Capital gains reported are the share of total income including capital gains. For example, the top decile (defined by income excluding capital gains) in 2000 earned 6.4% of their total income (including capital gains) in the form of capital gains.

In Panel B, tax returns are ranked by total income including full realized capital gains. The series report the share of total income (including capital gains) accruing in the form of capital gains.

Details on estimation are presented in Appendix Section C.

Table D1: Aggregate Series on Wage Income, 1972-2000

	Total number of employees	Number of families with wage	Total wage Income	Average individual wage income	Average family wage income	Consumer Price Index (CPI)
	in thousands	in thousands	in millions of 2000 dollars	in 2000 dollars	in 2000 dollars	(base 100 in 2000)
	(1)	(2)	(3)	(4)	(5)	(6)

2000	14,688	10,534	466,028	31,729	44,239	100.000

Notes: Total number of part-time and full time employees from number of tax returns reporting positive wages and salaries. Families defined as the sum of married couples and single individuals reporting positive wages and salaries.

Total employment income reported on tax returns (sum of wages and salaries, commissions from employment and other employment income). Average wage is column (5) over columns (2) or (3). All amounts are reported in 2000 Canadian dollars. See Appendix Section D for details.

Table D2: Shares of Wage Income for Upper Groups, 1972-2000

Notes: Shares computed from tax return statistics and total number of wage earners and total wage bill from Table D1. All details in Appendix Section D. For example, in 2000, the top 10% individual wage and salary earners earned 33.50% of total wages and salaries in Canada.

Notes: Stock options are reported as wage income on tax returns when exercised.

In Panel A, wage earners are ranked by wage income including stock option exercises (as in Table D2), and fraction of stock options (in total wage income) are reported in percent.

In Panel B, wage earners are ranked by wage income excluding stock options and wage income shares are computed excluding stock options (in both numerator and denominator).

In Panel C, wage earners are ranked by wage income excluding stock-options but wage income shares are computed including stock option (in both numerator and denominator).

In Panel D, wage earners are ranked by wage income excluding stock options and the share of stock options (in percent) in total wage income (including stock options) are reported.

All details in Appendix Section D.

Notes: Computations by authors based on gross income interpolations (reported in Table B4) and tax law for each year.

Marginal tax rates are calculated assuming exemptions for a married person with two dependents and average deductions by gross income level. Before 1972, only the federal income tax rates are reported as these included provincial income tax rates in most cases.

Beginning in 1972, the reported income rates include then-applicable provincial income tax, assuming residence in the largest province, Ontario. All rates include applicable surtaxes and credits. All details in Appendix Section E.

Notes: Computations by authors based on tax return statistics. See Appendix Section E for details.

Average tax rate defined as ratio of total net taxes paid to total gross income reported (including taxable capital gains) for each group. Average tax rates reported include both Provincial and Federal taxes and surtaxes as well as all income tax credits and deductions.

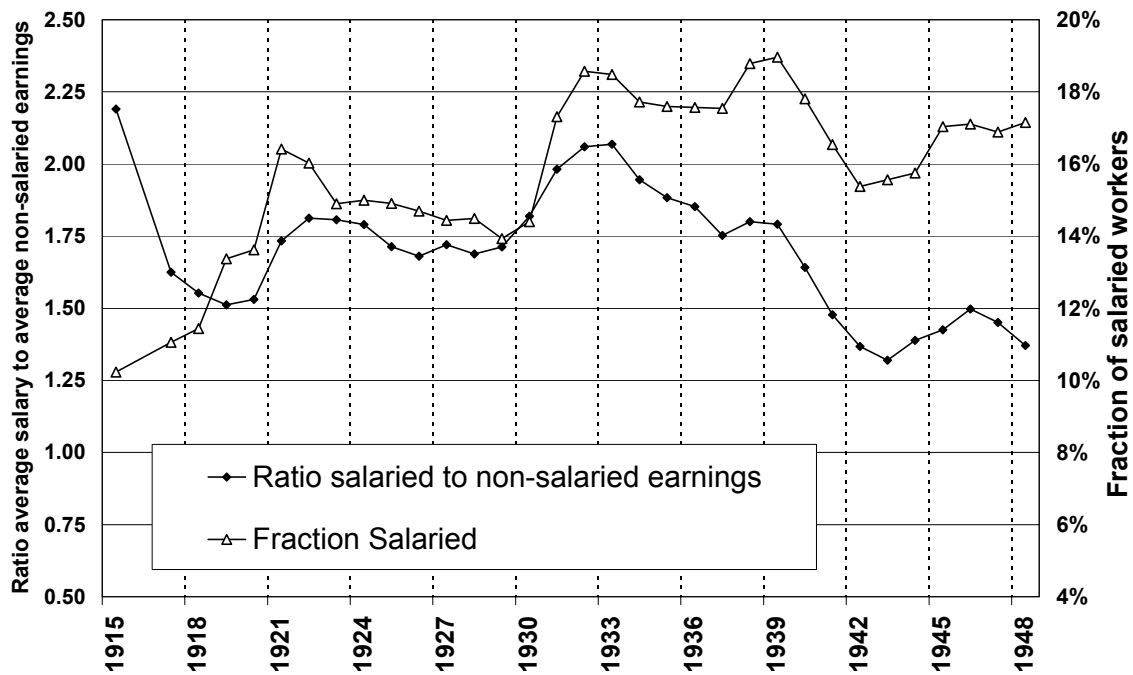

FIGURE 8

Salary vs. Non-salaried Earners in Manufacturing Sector in Canada, 1915-1948

Source: Series D280-287 in Urquhart and Buckley (1965) and The Canada Yearbook, various years.

Salaried workers are employees whose compensation is fixed on an annual basis

Non-salaried workers are employees whose compensation is fixed on an hourly, daily, or weekly basis

Number of non-salaried workers for years 1925 to 1930 has been reduced by 5% because of a change in the count of seasonal workers for these years.
